LASSO-TYPE RECOVERY OF SPARSE REPRESENTATIONS FOR HIGH-DIMENSIONAL DATA

By Nicolai Meinshausen and Bin Yu

UC Berkeley

The Lasso [28] is an attractive technique for regularization and variable selection for high-dimensional data, where the number of predictor variables \( p \) is potentially much larger than the number of samples \( n \). However, it was recently discovered [23, 38, 39] that the sparsity pattern of the Lasso estimator can only be asymptotically identical to the true sparsity pattern if the design matrix satisfies the so-called irrepresentable condition. The latter condition can easily be violated in applications due to the presence of highly correlated variables.

Here we examine the behavior of the Lasso estimators if the irrepresentable condition is relaxed. Even though the Lasso cannot recover the correct sparsity pattern, we show that the estimator is still consistent in the \( \ell_2 \)-norm sense for fixed designs under conditions on (a) the number \( s_n \) of non-zero components of the vector \( \beta_n \) and (b) the minimal singular values of the design matrices that are induced by selecting of order \( s_n \) variables. The results are extended to vectors \( \beta \) in weak \( \ell_q \)-balls with \( 0 < q < 1 \). Our results imply that, with

*We would like to thank Noureddine El Karoui and Debasish Paul for pointing out interesting connections to Random Matrix theory. Some results of this manuscript have been presented at the Oberwolfach workshop “Qualitative Assumptions and Regularization for High-Dimensional Data”. Nicolai Meinshausen is supported by DFG (Deutsche Forschungsgemeinschaft) and Bin Yu is partially supported by a Guggenheim fellowship and grants NSF DMS-0605165 (06-08), NSF DMS-03036508 (03-05) and ARO W911NF-05-1-0104 (05-07).
high probability, all important variables are selected. The set of selected variables is a useful (meaningful) reduction on the original set of variables \(p_n > n\). Finally, our results are illustrated with the detection of closely adjacent frequencies, a problem encountered in astrophysics.

1. Introduction. The Lasso was introduced by Tibshirani [28] and has since been proven to be very popular and well studied [18, 32, 38, 39]. Some reasons for the popularity might be that the entire regularization path of the Lasso can be computed efficiently [12, 24], that Lasso is able to handle more predictor variables than samples and produces sparse models which are easy to interpret. Several extensions and variations have been proposed [4, 21, 33, 37, 39].

1.1. Lasso-type estimation. The Lasso estimator, as introduced by [28], is given by

\[
\hat{\beta}^\lambda = \arg\min_{\beta} \|Y - X_\beta\|_2^2 + \lambda\|\beta\|_1,
\]

where \(X = (X_1, \ldots, X_p)\) is the \(n \times p\) matrix whose columns consist of the \(n\)-dimensional fixed predictor variables \(X_k, k = 1, \ldots, p\). The vector \(Y\) contains the \(n\)-dimensional set of real-valued observations of the response variable.

The distribution of Lasso-type estimators has been studied in Knight and Fu [18]. Variable selection and prediction properties of the Lasso have been studied extensively for high dimensional data with \(p \gg n\), a frequently encountered challenge in modern statistical applications. Some studies [e.g. 13, 31] have focused mainly on the behavior of prediction loss. Much recent work aims at understanding the Lasso estimates from the point of view of
model selection, including Meinshausen and Bühlmann [23], Donoho et al. [10], Zhao and Yu [38], Candes and Tao [4] and Zou [39]. For the Lasso estimates to be close to the model selection estimates when the data dimensions grow, all the aforementioned papers assumed a sparse model and used various conditions that state that the irrelevant variables are not too correlated with the relevant ones. Incoherence is the terminology used in the deterministic setting of Donoho et al. [10] and “irrepresentability” is used in the stochastic setting (linear model) of Zhao and Yu [38]. Here we focus exclusively on the properties of the estimate of the coefficient vector under squared error loss and try to understand the behavior of the estimate under a relaxed irrepresentable condition (hence we are in the stochastic or linear model setting). The aim is to see whether the Lasso still gives meaningful models in this case.

More discussions on the connections with other works will be covered in Section 1.5 after notions are introduced to state explicitly what the irrepresentable condition is so that the discussions are clearer.

1.2. Linear Model. We assume a linear model for the observations of the response variable \( Y = (Y_1, \ldots, Y_n) \),

\[
Y = X\beta + \varepsilon, \tag{2}
\]

where \( \varepsilon = (\varepsilon_1, \ldots, \varepsilon_n) \) is a vector containing independently and identically distributed noise with \( E(\varepsilon_i) = 0 \). When there is a question of nonidentifiability for \( \beta \) when \( p > n \), we define \( \beta \) as

\[
\beta = \arg \min_{\{\beta: EY = X\beta\}} \|\beta\|_{\ell_1}. \tag{3}
\]
The aim is to recover the vector $\beta$ as well as possible from noisy observations $Y$. For the equivalence between $\ell_1$- and $\ell_0$-sparse solutions see for example Donoho [8], Donoho and Elad [9], Gribonval and Nielsen [14].

1.3. Recovery of the sparsity pattern and the irrepresentable condition. There is empirical evidence that many signals in high-dimensional spaces allow for a sparse representation. As an example, wavelet coefficients of images often exhibit exponential decay, and a relatively small subset of all wavelet coefficients allow a good approximation to the original image [17, 19, 20]. For conceptual simplicity, we assume in our regression setting first that the vector $\beta$ is sparse in the $\ell_0$-sense and many coefficients of $\beta$ are identically zero (this will later be relaxed). The corresponding variables have thus no influence on the response variable and could be safely removed. The sparsity pattern of $\beta$ is understood to be the sign function of its entries, with $\text{sign}(x) = 0$ if $x = 0$, $\text{sign}(x) = 1$ if $x > 0$ and $\text{sign}(x) = -1$ if $x < 0$. The sparsity pattern of a vector might thus look like

$$\text{sign}(\beta) = (+1, -1, 0, 0, +1, +1, -1, +1, 0, 0, \ldots),$$

distinguishing whether variables have a positive, negative or no influence at all on the response variable. It is of interest whether the sparsity pattern of the Lasso estimator is a good approximation to the true sparsity pattern. If these sparsity patterns agree asymptotically, the estimator is said to be sign consistent [38].

**Definition 1 (Sign consistency)** An estimator $\hat{\beta}^\lambda$ is sign consistent if and only if

$$P\{\text{sign}(\beta) = \text{sign}(\hat{\beta})\} \to 1 \quad n \to \infty.$$
It was shown independently in Zhao and Yu [38], Zou [39] in the linear model case and Meinshausen and Bühlmann [23] in a Gaussian Graphical Model setting that sign consistency requires a condition on the design matrix. The assumption was termed the irrepresentable condition in Zhao and Yu [38]. Let $C = n^{-1}X^TX$. The dependence on $n$ is neglected notationally.

**Definition 2 (Irrepresentable condition)** Let $K = \{k : \beta_k \neq 0\}$ be the set of relevant variables and let $N = \{1, \ldots, p\} \setminus K$ be the set of noise variables. The sub-matrix $C_{HK}$ is understood as the matrix obtained from $C$ by keeping rows with index in the set $H$ and columns with index in $K$. The irrepresentable condition is fulfilled if it holds element-wise that

$$|C_{NK}C_{KK}^{-1}\text{sign}(\beta_K)| < 1.$$

In Zhao and Yu [38], an additional strong irrepresentable condition is defined which requires that the above elements are not merely smaller than 1 but are uniformly bounded away from 1. Zhao and Yu [38], Zou [39] and Meinshausen and Bühlmann [23] show that the Lasso is sign consistent only if the irrepresentable condition holds.

**Proposition 1 (Sign consistency only under irrepresentable condition)**

Let Assumptions 1-4 in Section 2.2 be satisfied. Assume that the irrepresentable condition is not fulfilled. Then there exists no sequence $\lambda = \lambda_n$ such that the estimator $\hat{\beta}^{\lambda_n}$ is sign consistent.

In practice, it might be difficult to verify whether the condition is fulfilled. This led various authors to propose interesting extensions to the Lasso [22, 36, 39]. Before giving up on the Lasso altogether, however, we want to
examine in this paper in what sense the original Lasso procedure still gives sensible results, even if the *irrepresentable condition* is not fulfilled.

1.4. \( \ell_2 \)-consistency. The aforementioned studies showed that if the *irrepresentable condition* is not fulfilled, the Lasso cannot select the correct sparsity pattern. In this paper we show that the Lasso selects in these cases the non-zero entries of \( \beta \) and some not-too-many additional zero entries of \( \beta \) under relaxed conditions than the irrepresentable condition. The non-zero entries of \( \beta \) are in any case included in the selected model. Moreover, the size of the estimated coefficients allows to separate the few truly zero and the many non-zero coefficients. However, it is worth noting that in the extreme cases when the variables are linearly dependent, these relaxed conditions will be violated as well. In these situations, it is not sensible to use the \( \ell_2 \)-metric on \( \beta \) to assess Lasso. Other metrics are to be investigated in our future research.

Our main result shows the \( \ell_2 \)-consistency of the Lasso, even if the *irrepresentable condition* is relaxed. To be precise, an estimator is said to be \( \ell_2 \)-consistent if

\[
\| \hat{\beta} - \beta \|_{\ell_2} \to 0 \quad n \to \infty.
\]

Convergence rates will also be derived. An \( \ell_2 \)-consistent estimator is attractive, as important variables are chosen with high probability and falsely chosen variables have very small coefficients. The bottom line will be that even if the sparsity pattern of \( \beta \) cannot be recovered by the Lasso, we can still obtain a good approximation.
1.5. Related work. Here we discuss further the existing works on Lasso mentioned earlier on. Prediction loss for high-dimensional regression with Lipschitz loss functions under an \(\ell_1\)-penalty is examined in van de Geer [31]. Also bounds for the \(\ell_1\)-distance between the vector \(\beta\) and its Lasso estimate are derived. Similar interesting results as in van de Geer [31] are obtained for random designs and squared error loss in Bunea et al. [2], both in terms of prediction loss and \(\ell_1\)-metric. A difference with the model selection results in these papers is that we are able to obtain \(\ell_2\)-consistency for fixed designs even if the sparsity \(s_n\) (the number of non-zero coefficients) is growing almost as fast as \(n\), while the previous results need \(s_n = o(\sqrt{n})\), partly because they require a data-independent choice of the penalty parameter. The previous study of [1] considers fixed designs (as we do), and obtains very nice results, albeit limited to the setting \(p \leq n\), while we are interested in the high-dimensional case where the number \(p\) of predictor variables is possibly very much larger than the sample size \(n\). The recent work of [35] shows that the subspace spanned by the variables selected by Lasso is close to an optimal subspace. The results also imply that important variables are chosen with high probability, yet the distance between the Lasso estimator and the true vector is not considered. A “partial Riesz condition” is employed, which is nearly identical to our notion of incoherent design.

We would also like to compare the results of this manuscript briefly with results in Donoho [7] and Candes and Tao [4], as both of these papers derive bounds on the \(\ell_2\)-norm distance between \(\beta\) and \(\hat{\beta}\) for \(\ell_1\)-norm constrained estimators. In Donoho [7] the design is random and the random predictor variables are assumed to be independent. The results are thus not directly
comparable to the results derived here for general fixed designs. Nevertheless, results in Meinshausen and Bühlmann [23] suggest that the irrepresentable condition is with high probability fulfilled for independently normal distributed predictor variables. The results in Donoho [7] can thus not directly be used to study the behavior of the Lasso under a violated irrepresentable condition, which is our goal in the current manuscript.

Candes and Tao [4] study the properties of the so-called “Dantzig selector”, which is very similar to the Lasso, and derive remarkably sharp bounds on the $\ell_2$-distance between the vector $\beta$ and the proposed estimator $\hat{\beta}$. The results are derived under the condition of a Uniform Uncertainty Principle (UUP), which was introduced in Candes and Tao [3]. The UUP is a relaxation of the irrepresentable condition and is very similar to our assumptions on sparse eigenvalues in this manuscript. It would be of interest to study the connection between the Lasso and “Dantzig selector” further, as the solutions share many similarities.

2. Main assumptions and results. First, we introduce the notion of sparse eigenvalues, which will play a crucial role in providing bounds for the convergence rates of the Lasso estimator. Thereafter, the assumptions are explained in detail and the main results are given.

2.1. Sparse eigenvalues. The notion of sparse eigenvalues is not new and has been used before [8]; we merely intend to fixate notation. The $m$-sparse minimal eigenvalue of a matrix is the minimal eigenvalue of any $m \times m$-dimensional submatrix.

**Definition 3** The $m$-sparse minimal eigenvalue and $m$-sparse maximal eigen-
value of $C$ are defined as

$$
\phi_{\text{min}}(m) = \min_{\beta : \|\beta\|_{0} \leq m} \frac{\beta^T C \beta}{\beta^T \beta}, \quad \text{and} \quad \phi_{\text{max}}(m) = \max_{\beta : \|\beta\|_{0} \leq m} \frac{\beta^T C \beta}{\beta^T \beta}.
$$

The minimal eigenvalue of the unrestricted matrix $C$ is equivalent to $\phi_{\text{min}}(p)$. If the number of predictor variables $p$ is larger than sample size, $p > n$, this eigenvalue is zero, as $\phi_{\text{min}}(m) = 0$ for any $m > n$.

A crucial factor contributing to the convergence of the Lasso estimator is the behavior of the smallest $m$-sparse eigenvalue, where the number $m$ of variables over which the minimal eigenvalues is computed is roughly identical to the sparsity $s$ of the true underlying vector.

2.2. Assumptions for high-dimensional data. We make some assumptions to prove the main result for high-dimensional data. We understand the term “high-dimensional” to imply here and in the following that we have potentially many more predictor variables than samples, $p_n \gg n$. While we are mainly interested in the $p_n > n$ case, the results are also relevant for $p_n \leq n$ scenarios. First, a convenient technical assumption.

**Assumption 1** The predictor variables are normalized, $\|X_k\|_{2}^2 = n$ for all $k, n$ and

$$
\max_{k \in \mathbb{N}} \|X_k\|_{\infty} < \infty.
$$

As predictor variables are normalized in practice anyway, the first part of the assumption is not very restrictive. The second part is mostly a technical assumption and simplifies exposition.

**Assumption 2** The noise satisfies $E(\exp|\varepsilon_i|) < \infty$ and $E(\varepsilon_i^2) = \sigma^2$ for some $\sigma^2 > 0$. 
The assumption of exponential tail bounds for the noise is fairly standard and certainly covers the case of Gaussian errors.

**Assumption 3** There exists some $\sigma^2_y < \infty$ such that $E(Y_i^2) \leq \sigma^2_y$ for all $i \in \mathbb{N}$.

This assumption is equivalent to a re-scaling of the coefficient vectors $\beta$ so that the signal-to-noise ratio stays approximately constant for all values of $n$ in our triangular setup.

**Assumption 4** For all $n$, the maximal eigenvalue $\phi_{\max}(\min\{n,p\})$ for any selection of $\min\{n,p\}$ columns is bounded from above by some finite value. The minimal eigenvalue for any selection of $\min\{n,p\}$ columns is strictly positive, $\phi_{\min}(\min\{n,p\}) > 0$.

Both parts of the assumption could be relaxed at the cost of increased notational complexity. It might be interesting to check if the assumptions are reasonable for a random design matrix. The latter part of Assumption 4 is fulfilled with probability 1 if the distribution of the random predictor variables is non-singular. Consider now the first part of the assumption about a bounded maximal eigenvalue. To be specific, assume multivariate normal predictors. If the maximal eigenvalue of the population covariance matrix, which is induced by selecting $n$ variables, is bounded from above by an arbitrarily large constant, it follows by Theorem 2.13 Davidson and Szarek [6] or Lemma A3.1 in Paul [25] that the condition number of the induced sample covariance matrix observes a Gaussian tail bound. Using an entropy bound for the possible number of subsets when choosing $n$ out of $p$ variables, Assumption 4 is thus fulfilled with probability converging to 1 for $n \to \infty$. 
as long as \( \log p_n = o(n^\kappa) \) for some \( \kappa < 1 \), and is thus maybe not overly restrictive.

2.3. Incoherent designs. As apparent from the interesting discussion in Candès and Tao [4], one cannot allow arbitrarily large “coherence” between variables if one still hopes to recover the correct sparsity pattern. Assume that there are two vectors \( \beta \) and \( \tilde{\beta} \) so that the signal can be represented by either vector \( X\beta = X\tilde{\beta} \) and both vectors are equally sparse, say \( \|\beta\|_0 = \|\tilde{\beta}\|_0 = s \) and are not identical. We have no hope of distinguishing between \( \beta \) and \( \tilde{\beta} \) in such a case: if indeed \( X\beta = X\tilde{\beta} \) and \( \beta \) and \( \tilde{\beta} \) are not identical, it follows that the minimal sparse eigenvalue \( \phi_{\min}(2s) = 0 \) vanishes as \( X(\beta - \tilde{\beta}) = 0 \) and \( \|\beta - \tilde{\beta}\|_0 \leq 2s \). The sparse minimal eigenvalue of a selection of order \( s \) variables indicates thus if we have any hope of recovering the true sparse underlying vector from noisy observations. A design is called \( m_n \)-incoherent in the following if the minimal eigenvalue of a collection of \( m_n \) variables is bounded from below by a constant.

**Definition 4 (\( m_n \)-incoherent designs)** Let \( m_n \) be a sequence with \( m_n = o(n) \) for \( n \to \infty \). A design is called incoherent for \( m_n \) if the minimal eigenvalue of a collection of \( m_n \) variables is bounded from below, that is if

\[
\liminf_{n \to \infty} \phi_{\min}(m_n) > 0.
\]

Our main result will require a \( s_n \log n \)-incoherent design. Most of the previous results on Lasso and related \( \ell_1 \)-constrained estimators have used similar, if slightly stronger, concepts.

Donoho and Huo [11] defined the mutual coherence \( M \) between two orthonormal basis as the maximal absolute value of the inner product of two
elements in the two orthonormal basis. One could extend this definition to arbitrary dictionaries where basis elements are scaled to have unit norm. Under the common assumption $M = O(1/n)$, the design is certainly incoherent in the meaning above, as the eigenvalue of any selection of order $s_n$ variables, with $s_n = o(n)$, will be bounded from below by a constant for sufficiently large values of $n$. The notion of incoherence above covers thus a wider spectrum.

Candes and Tao [4] use a Uniform Uncertainty Principle (UUP) to discuss the convergence of the so-called Dantzig selector. The UUP can only be fulfilled if the minimal eigenvalue of a selection of $s_n$ variables is bounded from below by a constant, where $s_n$ is again the number of non-zero coefficients of $\beta$. In the original version of, a necessary condition for (UUP) is

$$\phi_{\min}(s_n) + \phi_{\min}(2s_n) + \phi_{\min}(3s_n) > 2.$$  

In some sense, this requirement is weaker than $s_n \log n$-incoherent design as the minimal eigenvalues are calculated over maximally $3s_n$ instead of $s_n \log n$ variables. In another sense, $s_n \log n$-incoherent design is weaker as the eigenvalue can be bounded from below by an arbitrarily small constant.

Incoherent designs and the irrepresentable condition. One might ask in what sense the notion of incoherent designs is more general than the irrepresentable condition. At first, it might seem like we are simply replacing the strict condition of irrepresentable condition by a similarly strong condition on the design matrix.

Consider first the classical case of a fixed number $p$ of variables. If the covariance matrix $C = C_n$ is converging to a positive definite matrix for large
sample sizes, the design is automatically incoherent. On the other hand, it is easy to violate the irrepre- sentable condition in this case; for examples see Zou [39].

The notion of incoherent designs is only a real restriction in the high-dimensional case with \( p_n > n \). Even then, it is clear that the notion of incoherence is a relaxation from irrepre- sentable condition, as the irrepre- sentable condition can easily be violated even though all sparse eigenvalues are bounded well away from zero.

2.4. Main result for high-dimensional data \((p_n > n)\). Before we state our main result, we would like to use and explain the concept of active variables [12, 24] so that the penalty parameter has a useful interpretation as an upper bound on the number of active variables.

Active variables. Let \( G^\lambda \) be the \( p \)-dimensional gradient vector with respect to \( \beta \) of the squared error loss, \( G^\lambda = (Y - X \hat{\beta}^\lambda)^T X \), where \( \hat{\beta}^\lambda \) is the Lasso estimator. It follows by the KKT conditions or, alternatively, results in Osborne et al. [24] or Efron et al. [12] that the maximum of the absolute values of the components \( G^\lambda = (G_1^\lambda, \ldots, G_p^\lambda) \) is bounded by \( \lambda \),

\[
\max_{1 \leq k \leq p} |G_k^\lambda| \leq \lambda.
\]

We call variables with maximal absolute value of the gradient active variables. The set of active variables is denoted by

\[
A_\lambda := \{k : |G_k^\lambda| = \lambda\}.
\]

The number of selected variables (variables with a non-zero coefficient) is at most as large as the number of active variables, as any variable with a
non-zero estimated coefficient has to be an active variable [24]. In Lemma 2, we derive an upper probabilistic bound on the number of active variables when setting the penalty parameter to \( \lambda \). Set

\[
m_\lambda := \sigma_y^2 \phi_{\max} \frac{n^2}{\lambda^2},
\]

where \( \phi_{\max} = \phi_{\max}(\min\{n, p\}) \) is the bounded maximal eigenvalue of a selection of \( \min\{n, p\} \) variables. Let \( \lambda_n \) be a sequence of penalty parameters. Then, with probability converging to 1 for \( n \to \infty \), we have that \( |A_{\lambda_n}| \leq m_{\lambda_n} \). Instead of the penalty parameter \( \lambda \), we will often use the equivalent value of \( m_\lambda \), as it offers in our opinion the better intuition.

**Main result.** We will discuss the implications of the theorem after the proof, as its interpretation might not be inaccessible at first.

**Theorem 1 (Convergence in \( \ell_2 \)-norm)** Let Assumptions 1-4 be satisfied and assume the \( s_n \log n \)-incoherent design condition (6). Let \( m_{\lambda_n} \) be the bound (8) on the number of active variables under penalty parameter \( \lambda_n \).

The \( \ell_2 \)-norm of the error is then bounded for \( n \to \infty \) as

\[
\|\beta - \hat{\beta}_{\lambda_n}\|_2^2 \leq O_p \left( \frac{\log p_n}{n} \frac{m_{\lambda_n}}{\phi_{\max}^2(m_{\lambda_n})} \right) + O \left( \frac{s_n}{m_{\lambda_n}} \right).
\]

A proof is given in Section 3.

**Remark 1** It might be of interest to compare the results for variance and bias with equivalent results for orthogonal designs. In the case of orthogonal designs, each OLS-coefficient \( \hat{\beta}_k^0 \), \( k = 1, \ldots, p \) is soft-thresholded by the quantity \( n^{-1} \lambda_n \) to get \( \hat{\beta}_k^\lambda \). The squared bias of coefficients with \( |\beta_k| \gg n^{-1} \lambda_n \) is thus \( n^{-2} \lambda_n^2 \) (under the condition that \( n \) is sufficiently large, so that \( |\hat{\beta}_k^0| \geq \)).
\( n^{-1} \lambda_n \) with high probability). The total squared bias is thus \( s_n/m_{\lambda_n} \), which is identical to the order we derive for incoherent designs so the bound cannot be improved in general.

The variance part can also be compared to the variance of an estimator for orthogonal designs, which is proportional to \( m_{\lambda_n}/n \), the number of selected parameters divided by the sample size. In our result, we get an additional \( \log p_n \) factor, which stems from the fact that the subset of \( m_{\lambda_n} \) variables can be chosen among \( p_n \) variables. An additional factor of the reciprocal of \( \phi_{\min}^2(m_{\lambda_n}) \) adjusts for correlated designs.

Remark 2 It can be seen from the proofs that non-asymptotic bounds can be obtained with essentially the same results. As the constants of the non-asymptotic bounds are not very tight, we choose to present only the asymptotic result for clarity of exposition.

Organization of the remainder. The main question of concern for us is: under what circumstances can we find a sequence \( m_{\lambda_n} \) such that both the variance and bias term vanish asymptotically? If such a sequence exists, then we know that there is a sequence of penalty parameters \( \lambda_n \) so that

\[
\| \beta - \hat{\beta}_{\lambda_n} \|_{\ell_2} \rightarrow 0 \quad \text{as} \quad n \rightarrow \infty.
\]

Sufficient conditions for \( \ell_2 \)-consistency for \( \ell_0 \)-sparse vectors are derived in the following section. Thereafter results will be extended to vectors in weak \( \ell_q \)-balls. We will define the notion of effective sparsity and show that there is a one-to-one correspondence between the results for \( \ell_0 \)-sparse vectors and vectors in weak \( \ell_q \)-balls.
Lastly, a major implication of the results is shown, namely that the Lasso can be tuned to reliably pick all important variables if selecting a small subset of the total number of variables. As already know, some unimportant variables will unfortunately also be included in this set, but can be removed in a second stage.

2.5. $\ell_2$-consistency. We can immediately derive sufficient conditions for $\ell_2$-consistency in the sense of (4), asking under what circumstances there exists a penalty parameter sequence $\lambda_n$ so that $\|\beta - \hat{\beta}_{\lambda_n}\|_{\ell_2}$ converges in probability to 0 for large values of the sample size $n$. The following corollary can be derived from Theorem 1 by choosing $m_{\lambda_n} = s_n \log n$, using the incoherence assumption (6).

Corollary 1 ($\ell_2$-consistency) Let the assumptions of Theorem 1 be satisfied. The Lasso estimator is $\ell_2$-consistent under the condition that

$$s_n \log p_n \left( \frac{\log n}{n} \right) \to 0 \quad n \to \infty.$$

The result allows thus for the number of relevant variables $s_n$ to grow almost as fast as the number of samples $n$ if $p_n$ is not exponential in $n$, while still enjoying $\ell_2$-consistency.

Remark 3 To achieve the most general result for $\ell_2$-consistency, the rate $\lambda_n$ of the penalty parameter has to depend on the unknown sparsity $s_n$. The results offer thus not so much help in picking the correct penalty parameter, but merely states that somewhere along the solutions paths (when varying $\lambda$) there is a solution close to the true vector. How to choose the penalty parameter in a data driven way is further research.
Under less general circumstances, we can achieve $\ell_2$-consistency with a fixed penalty parameter sequence that does not depend on the unknown smoothness. Specifically, if limiting the growth rate of $s_n, p_n$ to be $s_n \ll n^{\rho_1}$ and $n/\log p_n \gg n^{\rho_2}$ for some $0 \leq \rho_1 < \rho_2 < 1$, then any sequence $m_{\lambda_n} \asymp n^\rho$ with $\rho_1 < \rho < \rho_2$ achieves $\ell_2$-consistency, irrespective of the actual sparsity, as long as the stronger incoherence assumption $\liminf_{n \to \infty} \phi_{\min}(m_{\lambda_n}) > 0$ is fulfilled.

2.6. Some results for weak $\ell_q$-balls. So far, we have been assuming that the vector $\beta$ is sparse in an $\ell_0$-sense, with most entries of $\beta$ being identically zero. This is a conceptually simple assumption. It is easy to formulate the problem and understand the results for the $\ell_0$-sparse setting. In the end, however, it might be overly simplistic to assume that most of the entries are identically zero. It is perhaps more interesting to assume that most of the entries are very small, as is the case for wavelet coefficients of natural images [17, 19, 20]. We can for example consider the case that the vector $\beta$ lies in a weak $\ell_q$-ball with $0 < q < 2$. Let $|\beta(1)| \geq |\beta(2)| \geq \ldots \geq |\beta(p)|$ be the ordered entries of $\beta$. The vector $\beta$ lies in a weak $\ell_1$-ball if there exists a constant $s_{q,n} > 0$ such that

$$\forall 1 \leq k \leq p : \quad |\beta(k)| \leq s_{q,n} k^{-1/q}. \tag{11}$$

If a vector $\beta$ has a $\ell_q$-(quasi-)norm $\|\beta\|_{\ell_q}$, then it also lies in a weak $\ell_q$-ball with the sparsity $s_{q,n}$, that is

$$s_{q,n} \leq \|\beta\|_{\ell_q}.$$

In the $\ell_q$-sparse setting, it does not make sense trying to recover the correct sparsity pattern, as all coefficients are in general different from zero. We
can, however, ask if the most important coefficients are recovered, neglecting coefficients with very small absolute value.

Consider the case $0 < q < 1$, where coefficients decay faster than $1/k$. As can be seen in the following, the bound on the $\ell_2$-distance between $\beta$ and its estimate $\hat{\beta}^\lambda$ is very similar to the $\ell_0$-sparse setting.

**Effective Sparsity.** There is a simple connection between the results for $\ell_0$-sparse and $\ell_q$-sparse vectors. Specifically, we are interested in settings where $\ell_2$-consistency of the Lasso estimator can be achieved. If we define the effective sparsity as $s_{q,n}$ raised to the power of $2q/(2-q)$, the results of the $\ell_0$-sparse setting are directly applicable to the $\ell_q$-sparse setting with $0 < q < 1$.

**Definition 5 (Effective sparsity)** The effective sparsity $s_{\text{eff}}^n$ of a vector $\beta$ in a weak $\ell_q$-ball with sparsity $s_{q,n}$ is defined as

$$s_{\text{eff}}^n = s_{q,n}^{\frac{2q}{2-q}}. \tag{12}$$

To motivate the notion of effective sparsity, suppose that the decay of the absolute value of the components of $\beta$ is fast. A good approximation to $\beta$ in the $\ell_2$-sense can then be obtained by retaining just a few large components of $\beta$. Assume that the entries of $\beta$ are ordered so that $|\beta_1| \geq |\beta_2| \geq \ldots \geq |\beta_p|$. Let $\tilde{\beta}^d$ be the approximation that retains only the $d$ largest components,

$$\tilde{\beta}_k^d = \begin{cases} 
\beta_k & k \leq d \\
0 & d > s
\end{cases}.$$ 

The effective sparsity measures the minimal number $d = d_n$ of non-zero components necessary to obtain an approximation $\tilde{\beta}^{d_n}$ of $\beta$ that satisfies

$$\|\tilde{\beta}^{d_n} - \beta\|_{\ell_2} \to 0 \quad n \to \infty. \tag{13}$$
To be precise, let $\mathcal{B}$ be the set $\mathcal{B} = \{ \beta : \| \beta \|_{\ell_q} \leq s_{q,n} \text{ for all } n \}$. Then, for any sequence $d_n$ which satisfies (13) for every vector $\beta \in \mathcal{B}$, the number of retained coefficients $d_n$ needs to be at least of the same order as the effective sparsity, that is $\liminf_{n \to \infty} d_n / s_{n}^{\text{eff}} > 0$. On the other hand, retaining exactly $s_{n}^{\text{eff}}$ components satisfies (13) for every vector $\beta \in \mathcal{B}$. A proof of this is straightforward but omitted here. The notion of effective sparsity is thus inherent to the nature of the problem.

The definition of effective sparsity will be helpful in the following. Suppose we want to see whether $\ell_2$-consistency can be achieved for vectors in a weak $\ell_q$-ball with sparsity $s_{q,n}$. The effective sparsity of this setting can then be calculated according to (12). We can then look at the $\ell_0$-sparse vectors, where the number of non-zero entries is set to the effective sparsity of the original problem. If $\ell_2$-consistency can be achieved for the $\ell_0$-sparse setting, it can also be achieved for the $\ell_q$-sparse setting. With the notion of effective sparsity, a bound on the $\ell_2$-distance between the Lasso estimator and the true vector can be derived.

**Theorem 2** Let the assumptions of Theorem 1 be fulfilled, except that the vector $\beta$ is only assumed to be in a weak $\ell_q$-ball for some $0 < q < 1$. Let again $m_{\lambda_n}$ be the bound on the number of active variables (8) and assume $m_{n}$-incoherent design. Then

$$\| \beta - \hat{\beta}_{\lambda_n} \|_{\ell_2}^2 = O_p\left( \frac{\log \log n}{m_{\lambda_n}} \right) + O\left( \left( \frac{s_{n}^{\text{eff}}}{m_{\lambda_n}} \right)^{1-q/2} \right).$$

A proof is given in Section 4.

The place of the sparsity measure $s_n$, the number of non-zero elements, is now taken by the effective sparsity $s_{n}^{\text{eff}}$. The implications of Theorem 2 are
similar to those of $\ell_0$-sparse vectors. The Lasso is thus able to recover not only $\ell_0$-sparse vectors but also vectors which are sparse in the sense of lying in a weak $\ell_q$-ball for some small value of $q$.

2.7. Sign consistency with two-step procedures. The results show that the Lasso estimator can be made sign consistent in a two-step procedure even if the irrepresentable condition is relaxed but under the assumption that non-zero coefficients of $\beta$ are “sufficiently” large. One possibility is hard-thresholding of the obtained coefficients, neglecting variables with very small coefficients. This effect has already been observed empirically in [30]. Other possibilities include soft-thresholding and relaxation methods such as the Gauss-Dantzig selector [4] or the Relaxed Lasso [22] with an additional thresholding step.

We start with a corollary that follows directly from Theorem 1, stating that important variables are chosen with high probability. Let $L$ be the subset of large coefficients and $Z$ be the subset of zero coefficients,

$$L := \{ k : \beta_k^1 \gg \frac{s_n \log p_n}{n} \},$$
$$Z := \{ k : \beta_k = 0 \}$$

where $a_n \gg b_n$ is again meant to imply that $a_n/b_n \to \infty$ for $n \to \infty$. The following corollary states that the Lasso can distinguish between variables in $L$ and $Z$.

**Corollary 2** Let the assumptions of Theorem 2 be satisfied and assume $\sqrt{s_n n}$-incoherent design. There exists a penalty sequence $\lambda_n$ such that, with probability converging to 1 for $n \to \infty$, the absolute value of coefficients in
L is larger than the absolute value of any coefficient in $Z$, 

$$\forall k \in L, k_z \in Z : \quad |\hat{\beta}_{k_z}^{\lambda_n}| < |\hat{\beta}_{k}^{\lambda_n}|.$$ 

**Proof.** The proof follows from the results of Theorem 1. Event (14) is fulfilled if $\|\hat{\beta}^{\lambda_n} - \beta\|_{\infty} \leq \min_{k \in L} |\beta_k|$. Choosing a penalty sequence $\lambda_n$ with $m_{\lambda_n}^2 = ns_n \log^{-1} p_n$ yields with Theorem 1 that $\|\hat{\beta}^{\lambda_n} - \beta\|_{\ell_2} = O_p(n^{-1}s_n \log p_n)$. The bound on the $\ell_2$-distance gives trivially the identical bound on the $\ell_{\infty}$-distance between $\hat{\beta}^{\lambda_n}$ and $\beta$. Furthermore, by definition of the set $L$, $\min_{k \in L} |\beta_k| \gg (n^{-1}s_n \log p_n)^{1/4}$, which compiles the proof. 

**Remark 4** The corollary implies that variables with sufficiently large regression coefficients are chosen with very large probability by the Lasso, that is for $n \to \infty$, 

$$P(\forall k \in L : \hat{\beta}_{k}^{\lambda_n} \neq 0) \to 1.$$ 

As also some additional unwanted variables are chosen (which cannot be avoided if the irrepresentable condition is violated), the result implies that the Lasso is successful in narrowing down the choice of $p_n \gg n$ variables to a subset of variables with cardinality much smaller than $n$ (at least of smaller order than $\sqrt{ns_n}$). All important variables are with large probability in this much smaller Lasso-selected subset. A two-step procedure would try to filter out those important variables from the selected subset. Consistent variable selection could for example be achieved by simple thresholding of small coefficients in the initial Lasso estimator. 

**Remark 5** It is apparent that the large bias of the Lasso estimator allows only for a slow rate of decay of coefficients in the set $L$. To alleviate this
problem, one could first reduce the bias of the selected coefficients and apply thresholding after this relaxation step. Even though we view this bias-reduction step as important, we refrain from giving more details due to space constraints.

In conclusion, even though one cannot achieve sign consistency in general with just a single Lasso estimation, it can often be achieved in a two-stage procedure.

3. Proof of Theorem 1. The first term on the right hand side of (9) is a variance-type and the second term represent a bias-type contribution. Let $\beta^*_n$ be the estimator under the absence of noise, that is $\beta^* = \hat{\beta}^{\lambda,0}$, where $\hat{\beta}^{\lambda,\xi}$ is defined as in (30). The $\ell_2$-distance can then be bounded by $\|\hat{\beta}^\lambda - \beta\|_{\ell_2}^2 \leq 2\|\hat{\beta}^\lambda - \beta^\lambda\|_{\ell_2}^2 + 2\|\beta^\lambda - \beta\|_{\ell_2}^2$. The first term on the right hand side represents the variance of the estimation, while the second term represents the bias. The bound on the variance term follows by Lemma 6. The bias contribution follows directly from Lemma 1. □

3.1. Part I of Proof: Bias. Let $K$ be the set of non-zero elements of $\beta$, that is $K = \{k : \beta_k \neq 0\}$. The cardinality of $K$ is again denoted by $s = s_n$. For the following, let $\beta^\lambda$ be the estimator $\hat{\beta}^\lambda$ under the absence of noise, $\sigma = 0$. The solution $\beta^\lambda$ can, for each value of $\lambda$, be written as $\beta^\lambda = \beta + \gamma^\lambda$, where

$$\gamma^\lambda = \arg\min_{\zeta \in \mathbb{R}^p} f(\zeta),$$

(15)
where the function $f(\zeta)$ is given by

$$
(16) \quad f(\zeta) = n\zeta^T C \zeta + \lambda \sum_{k \in K^c} |\zeta_k| + \lambda \sum_{k \in K} (|\beta_k + \zeta_k| - |\beta_k|).
$$

The vector $\gamma^\lambda$ is the bias of the Lasso estimator. We derive first a bound on the $\ell_2$-norm of $\gamma^\lambda$.

**Lemma 1** Let $\kappa > 0$ be the minimal eigenvalue with $\liminf_{n \to \infty} \phi_{\min}(s_n \log s_n) > \kappa$. The $\ell_2$-norm of $\gamma^\lambda$, as defined in (15), is bounded for sufficiently large values of $n$ by

$$
\|\gamma^\lambda\|_{\ell_2} \leq \frac{\lambda n^{\sqrt{s_n}}}{\kappa}.
$$

**Proof.** We write in the following $\gamma$ instead of $\gamma^\lambda$ for notational simplicity.

Let $\gamma(K)$ be the vector with coefficients $\gamma_k(K) = \gamma_k 1\{k \in K\}$, that is $\gamma(K)$ is the bias of the truly non-zero coefficients. Analogously, let $\gamma(K^c)$ be the bias of the truly zero coefficients with $\gamma_k(K^c) = \gamma_k 1\{k \notin K\}$. Clearly, $\gamma = \gamma(K) + \gamma(K^c)$. The value of the function $f(\zeta)$, as defined in (16), is 0 if setting $\zeta = 0$. For the true solution $\gamma^\lambda$, it follows hence that $f(\gamma^\lambda) \leq 0$.

Hence, using that $\zeta^T C \zeta \geq 0$ for any $\zeta$,

$$
(17) \quad \|\gamma(K^c)\|_{\ell_1} = \sum_{k \in K^c} |\zeta_k| \leq \sum_{k \in K} (|\beta_k + \zeta_k| - |\beta_k|) \leq \|\gamma(K)\|_{\ell_1}.
$$

As $\|\gamma(K)\|_{\ell_0} \leq s_n$, it follows that $\|\gamma(K)\|_{\ell_1} \leq \sqrt{s_n} \|\gamma(K)\|_{\ell_2} \leq \sqrt{s_n} \|\gamma\|_{\ell_2}$ and hence, using (17),

$$
(18) \quad \|\gamma\|_{\ell_1} \leq 2\sqrt{s_n} \|\gamma\|_{\ell_2}.
$$

This result will be used further below. We use now again that $f(\gamma^\lambda) \leq 0$ (as $\zeta = 0$ yields the upper bound $f(\zeta) = 0$). Using the previous result that
\[ \| \gamma(K) \|_{\ell_1} \leq \sqrt{s_n} \| \gamma \|_{\ell_2}, \] 
and ignoring the non-negative term \( \| \gamma(K^c) \|_{\ell_1} \), it follows that

\[ n \gamma^T C \gamma \leq \lambda \sqrt{s_n} \| \gamma \|_{\ell_2}. \]  

Consider now the term \( \gamma^T C \gamma \). Bounding this term from below and plugging the result into (19) will yield the desired upper bound on the \( \ell_2 \)-norm of \( \gamma \). Let \( |\gamma(1)| \geq |\gamma(2)| \geq \ldots \geq |\gamma(p)| \) be the ordered entries of \( \gamma \).

Let \( \{ u_n \}_{n \in \mathbb{N}} \) be a sequence of positive integers, to be chosen later, and define the set of the “\( u_n \)-largest coefficients” as \( U = \{ k : |\gamma_k| \geq |\gamma_{(u_n)}| \} \). Define analogously to above the vectors \( \gamma(U) \) and \( \gamma(U^c) \) by \( \gamma_k(U) = \gamma_k1 \{ k \in U \} \) and \( \gamma_k(U^c) = \gamma_k1 \{ k \notin U \} \). The quantity \( \gamma^T C \gamma \) can be written as

\[ \gamma^T C \gamma = (\gamma(U)^T C \gamma(U) = \| a + b \|_{\ell_2}^2, \]

where \( a := n^{-1/2}X \gamma(U) \) and \( b := n^{-1/2}X \gamma(U^c) \). Then

\[ \gamma^T C \gamma = a^T a + 2b^T a + b^T b \geq \| a \|_{\ell_2}^2 - 2\| a \|_{\ell_2} \| b \|_{\ell_2}. \]

As \( \gamma(U) \) has by definition only \( u_n \) non-zero coefficients,

\[ \| a \|_{\ell_2}^2 = \| \gamma(U)^T C \gamma(U) \|_{\ell_2}^2 \geq \phi_{\text{min}}(u_n) \| \gamma(U) \|_{\ell_2}^2 = \phi_{\text{min}}(u_n)(\| \gamma \|_{\ell_2}^2 - \| \gamma(U^c) \|_{\ell_2}^2). \]

As \( \gamma(U^c) \) has at most \( n \) non-zero coefficients,

\[ \| b \|_{\ell_2}^2 = \| \gamma(U^c)^T C \gamma(U^c) \|_{\ell_2}^2 \leq \phi_{\text{max}}(n) \| \gamma(U^c) \|_{\ell_2}^2 \]

Using (22) and (23) in (21),

\[ \| a \|_{\ell_2}^2 - 2\| a \|_{\ell_2} \| b \|_{\ell_2} \geq \phi_{\text{min}}(u_n)(\| \gamma \|_{\ell_2}^2 - \| \gamma(U^c) \|_{\ell_2}^2) \]

\[ -2\sqrt{\phi_{\text{min}}(u_n)\phi_{\text{max}}(n)} \| \gamma \|_{\ell_2} \| \gamma(U^c) \|_{\ell_2}. \]
and hence

\begin{equation}
\gamma^T C \gamma \geq \phi_{\min}(u_n) \|\gamma\|_2^2 \left(1 - 2 \sqrt{\frac{\phi_{\max}(n)}{\phi_{\min}(u_n)}} \frac{\|\gamma(U^c)\|_2}{\|\gamma\|_2} - \frac{\|\gamma(U^c)\|_2^2}{\|\gamma\|_2^2}\right).
\end{equation}

Before proceeding, we need to bound the norm \(\|\gamma(U^c)\|_2\) as a function of \(u_n\). Assume for the moment that the \(\ell_1\)-norm \(\|\gamma\|_1\) is identical to some \(\ell > 0\). Then it holds for every \(k = 1, \ldots, p\) that \(\gamma(k) \leq \ell/k\). Hence,

\begin{equation}
\|\gamma(U^c)\|_2^2 \leq \|\gamma\|_1^2 \sum_{k=u_n+1}^p \frac{1}{k^2} \leq (4s_n \|\gamma\|_2^2) \frac{1}{u_n},
\end{equation}

having used the result (18) from above that \(\|\gamma\|_1 \leq 2\sqrt{s_n} \|\gamma\|_2\). Plugging this result into (24),

\begin{equation}
\gamma^T C \gamma \geq \phi_{\min}(u_n) \|\gamma\|_2^2 \left(1 - 2 \sqrt{\frac{4s_n \phi_{\max}(n)}{u_n \phi_{\min}(u_n)}} - \frac{4s_n}{u_n}\right).
\end{equation}

Choosing a sequence \(u_n = s_n \log n\), it holds with the assumption \(\lim \inf_{n \to \infty} \phi_{\min}(s_n \log n) > \kappa\), that for sufficiently large values of \(n\), by the assumption of a bounded maximal eigenvalue \(\phi_{\max}(n)\),

\[\gamma^T C \gamma \geq \kappa \|\gamma\|_2^2.\]

Using the last result together with (19), which says that \(\gamma^T C \gamma \leq n^{-1} \lambda \sqrt{s_n} \|\gamma\|_2\), it follows that for large \(n\),

\[\|\gamma\|_2 \leq \frac{\lambda}{n} \frac{\sqrt{s_n}}{\kappa},\]

which completes the proof. \(\square\)

3.2. Part II of Proof: Variance. First, bounds for the number of selected and active variables are derived. These bounds are later used to assess the variance of the estimator under noisy observations.
A bounds on the number of active variables. A decisive part in the variance of the estimator is determined by the number of selected variables. Instead of directly bounding the number of selected variables, we derive bounds for the number of active variables. As any variable with a non-zero regression coefficient is also a active variable, these bounds lead trivially to bounds for the number of selected variables.

Let again $A_\lambda$ be the set of active variables,

$$A_\lambda = \{ k : |G^\lambda_k| = \lambda \}.$$  

The number of selected variables (variables with a non-zero coefficient) is at most as large as the number of active variables, as any variable with a non-zero estimated coefficient has to be an active variable \[24\].

**Lemma 2** With probability tending to 1 for $n \to \infty$, the number $|A_\lambda|$ of active variables of the estimator $\hat{\beta}^\lambda$ is bounded by

$$|A_\lambda| \leq \sigma_y^2 \phi_{\text{max}}(|A_\lambda|) \frac{n^2}{\lambda^2} \leq \sigma_y^2 \phi_{\text{max}}(\min\{n, p\}) \frac{n^2}{\lambda^2} := m_\lambda,$$

where $\phi_{\text{max}}(|A_\lambda|)$ is the bounded maximal eigenvalue of a selection of at most $|A_\lambda| \leq \min\{n, p\}$ variables.

**Proof.** Let $R(\lambda)$ be the vector residuals, $R(\lambda) = Y - X\hat{\beta}^\lambda$. For any $k$ in the $|A_\lambda|$-dimensional space spanned by the active variables,

$$|G^\lambda_k| = |R^T(\lambda)X_k| = \lambda.$$

Let $R^A(\lambda)$ be the projection $P^A R(\lambda)$ of the residuals $R(\lambda)$ into the $|A_\lambda|$-dimensional space spanned by the $|A_\lambda|$ active variables. Then, by (27),

$$\|X^T_A R^A(\lambda)\|_{L_2}^2 = \|X^T_A R(\lambda)\|_{L_2}^2 = |A_\lambda| \lambda^2.$$  

imsart-aos ver. 2006/10/13 file: lasso_sparse.tex date: December 6, 2006
As $R^A(\lambda)$ is the projection onto the space spanned by $|A_\lambda|$ active variables, it holds that for $|A_\lambda| \leq n$, with the notation $v = X_A^T R(\lambda)$,

$$R^A(\lambda) = X_A(X_A^T X_A)^{-1}v,$$

and hence

$$\|R^A(\lambda)\|_2^2 = v^T (X_A^T X_A)^{-1}v \geq \{n\phi_{\max}(|A_\lambda|)\}^{-1}\|v\|_2^2.$$

Using the result (28), it follows that $\|v\|_2^2 \geq |A_\lambda|^2$ and hence

$$\|R^A(\lambda)\|_2^2 \geq \{n\phi_{\max}(|A_\lambda|)\}^{-1}|A_\lambda|^2.$$

The sum of squared residuals is bounded uniformly over all subsets $M$ of the active variables by $\|R^A(\lambda)\|_2^2 \leq \|Y\|_2^2$. By assumption 3, it holds with probability converging to 1 for $n \to \infty$, that $\|Y\|_2^2 \leq n\sigma_y^2$, which completes the proof. \hfill \Box

**De-noised response.** We need for the following a little extension of the result above. Define for $0 < \xi < 1$ the de-noised version of the response variable,

$$\text{(29)} \quad Y(\xi) = X\beta + \xi \varepsilon.$$

We can regulate the amount of noise with the parameter $\xi$. For $\xi = 0$, only the signal is retained. The original observations with the full amount of noise are recovered for $\xi = 1$. Now consider for $0 \leq \xi \leq 1$ the estimator $\hat{\beta}^{\lambda,\xi}$,

$$\text{(30)} \quad \hat{\beta}^{\lambda,\xi} = \arg\min_\beta \|Y(\xi) - X\beta\|_2^2 + \lambda \|\beta\|_1.$$

The ordinary Lasso estimate is recovered under the full amount of noise so that $\hat{\beta}^{\lambda,1} = \hat{\beta}^\lambda$. Using the notation from the previous results, we can write
for the estimate in the absence of noise, $\hat{\beta}^{\lambda,0} = \beta^\lambda$. The definition of the de-noised version of the Lasso estimator will be helpful for the proof as it allows to characterize the variance of the estimator.

**Number of active variables for the de-noised estimator.** In analogy to the gradient $G^\lambda$ of the loss function, let $G^{\lambda,\xi}$ be the gradient vector with respect to $\beta$ of the squared error loss when estimating the de-noised version of the observations,

$$G^{\lambda,\xi} = (Y(\xi) - X\hat{\beta}^{\lambda,\xi})^T X.$$  

Variables are called again *active* if the absolute value of the respective gradient is equal to the maximal value $\lambda$. The *active variables* are denoted by $A_{\lambda,\xi}$. The result of Lemma 2 can now easily be shown to hold uniformly over all de-noised versions of the estimator.

**Lemma 3** With probability converging to 1 for $n \to \infty$, the number $|A_{\lambda,\xi}|$ of active variables of the de-noised estimator is bounded by

$$|A_{\lambda,\xi}| \leq \sigma_y^2 \frac{n^2}{\lambda^2} \phi_{\max}(|A_{\lambda,\xi}|).$$

**Proof.** The proof follows analogously to the proof of Lemma 2. In analogy to $R^A$, let $R^{A,\xi}$ be the projection of the residuals $Y(\xi) - X\hat{\beta}^{\lambda,\xi}$ onto the space spanned by the active variables. The bound $\|R^{A,\xi}\|_{\ell_2} \leq \sup_{0 \leq \xi \leq 1} \|Y(\xi)\|_{\ell_2}$ holds uniformly over all values of $\xi$ with $0 \leq \xi \leq 1$. By assumption 3, the term $n^{-1} \sup_{0 \leq \xi \leq 1} \|Y(\xi)\|_{\ell_2}$ is, with probability converging to 1 for $n \to \infty$, bounded by $\sigma_y^2$. The proof follows then exactly like the proof of Lemma 2.

$\square$
This uniform bound is used below to bound the variance of the Lasso estimator.

**Variance of restricted OLS.** Next, we consider the variance of the Lasso estimator as a function of the penalty parameter. Let \( \hat{\theta}^M \in \mathbb{R}^p \) be for every subset \( M \subseteq \{1, \ldots, p\} \) with \(|M| \leq n\) the restricted OLS-estimator of the noise vector \( \varepsilon \),

\[
\hat{\theta}^M = (X_M^T X_M)^{-1} X_M^T \varepsilon.
\]

First, we bound the \( \ell_2 \)-norm of this estimator. The result is useful for bounding the variance of the final estimator, based on the derived bound on the number of active variables.

**Lemma 4** The \( \ell_2 \)-norm of the restricted estimator \( \hat{\theta}^M \) is uniformly over all sets \( M \) with \(|M| \leq m_{\lambda_n}\), where \( m_{\lambda_n} \) is as defined in (8), bounded for \( n \to \infty \) by

\[
\max_{M: |M| \leq m_{\lambda_n}} \| \hat{\theta}^M \|_{\ell_2}^2 = O_p \left( \frac{\log p_n}{n \phi_{\min}^2 (m_{\lambda_n})} \right).
\]

**Proof.** It follows directly from the definition of \( \hat{\theta}^M \) that, for every \( M \) with \(|M| \leq m_{\lambda_n}\),

\[
\| \hat{\theta}^M \|_{\ell_2}^2 \leq \frac{1}{n^2 \phi_{\min}^2 (m_{\lambda_n})} \| X_M^T \varepsilon \|_{\ell_2}^2.
\]

It remains to be shown that, for \( n \to \infty \),

\[
\max_{M: |M| \leq m_{\lambda_n}} \| X_M^T \varepsilon \|_{\ell_2}^2 = O_p (m_{\lambda_n} n \log p_n).
\]

As \( E(\exp |\varepsilon_i|) < \infty \) and \( \max_k \| X_k \|_{\ell_\infty} < \infty \), it follows by Bernstein's inequality that \( |X_k^T \varepsilon|^2 = O_p(n) \) for every \( k \leq p_n \) and due to the exponential
tail bound

$$\max_{k \leq p_n} |X_k^T \varepsilon|^2 = O_p(n \log p_n);$$

and hence,

$$\max_{M: |M| \leq m_{\lambda_n}} \|X_M^T \varepsilon\|_2 \leq m_{\lambda_n} \max_{k \leq p_n} |X_k^T \varepsilon|^2 = O_p(n m_{\lambda_n} \log p_n).$$

Using this in conjunction with (33) completes the proof. □

Variance of estimate is bounded by restricted OLS variance. We show that the variance of the Lasso estimator can be bounded by the variances of restricted OLS estimators, using bounds on the number of active variables.

Lemma 5 If, for a fixed value of $\lambda$, the number of active variables of the de-noised estimators $\hat{\beta}^{\lambda, \xi}$ is for every $0 \leq \xi \leq 1$ bounded by $m$, then

$$\|\hat{\beta}^{\lambda, 0} - \hat{\beta}^{\lambda, 1}\|_2^2 \leq \max_{M: |M| \leq m} \|\hat{\theta}^M\|_2^2.$$  

Proof. The key in the proof is that the solution path of $\hat{\beta}^{\lambda, \xi}$, if increasing the value of $\xi$ from 0 to 1, can be expressed piecewise in terms of the restricted OLS solution. The set $M(\xi)$ of active variables is the set with maximal absolute gradient,

$$M(\xi) = \{k : |G_{\lambda, \xi}^k| = \lambda\}.$$  

Note that the estimator $\hat{\beta}^{\lambda, \xi}$ and also the gradient $G_{\lambda, \xi}^k$ are continuous functions in both $\lambda$ and $\xi$ [12]. Let $0 = \xi_1 < \xi_2 < \ldots < \xi_{L+1} = 1$ be the points of discontinuity of $M(\xi)$. At these locations, variables either join the active set or are dropped from the active set.
Fix some $j$ with $1 \leq j \leq J$. Denote by $M_j$ the set of active variables $M(\xi)$ for any $\xi \in (\xi_j, \xi_{j+1})$. We show in the following that the solution $\hat{\beta}^{\lambda, \xi}$ is for all $\xi$ in the interval $(\xi_j, \xi_{j+1})$ given by

$$\forall \xi \in (\xi_j, \xi_{j+1}): \quad \hat{\beta}^{\lambda, \xi} = \hat{\beta}^{\lambda, \xi_j} + (\xi - \xi_j)\hat{\theta}^{M_j},$$

where $\hat{\theta}^{M_j}$ is the restricted OLS estimator of noise, as defined in (32). The local effect of increased noise (larger value of $\xi$) on the estimator is thus to shift the coefficients of the active set of variables along the least squares direction.

Once (34) is shown, the claim follows by piecing together the piecewise linear parts and using continuity of the solution as a function of $\xi$ to obtain

$$\|\hat{\beta}^{\lambda, 0} - \hat{\beta}^{\lambda, 1}\|_2 \leq \sum_{j=1}^{J} \|\hat{\beta}^{\lambda, \xi_j} - \hat{\beta}^{\lambda, \xi_{j+1}}\|_2 \leq \max_{M: |M| \leq m} \|\hat{\theta}^{M}\|_2 \sum_{j=1}^{J} (\xi_{j+1} - \xi_j) = \max_{M: |M| \leq m} \|\hat{\theta}^{M}\|_2.$$

It thus remains to show (34). A necessary and sufficient condition for $\hat{\beta}^{\lambda, \xi}$ with $\xi \in (\xi_j, \xi_{j+1})$ to be a valid solution is that for all $k \in M_j$ with non-zero coefficient $\hat{\beta}^{\lambda, \xi}_k \neq 0$, the gradient is equal to $\lambda$ times the negative sign,

$$\hat{G}^{\lambda, \xi}_k = -\lambda \text{ sign}(\hat{\beta}^{\lambda, \xi}_k),$$

that for all variables with $k \in M_j$ with zero coefficient $\hat{\beta}^{\lambda, \xi}_k = 0$ the gradient is equal in absolute value to $\lambda$

$$|\hat{G}^{\lambda, \xi}_k| = \lambda,$$

and for variables $k \notin M_j$ not in the active set,

$$|\hat{G}^{\lambda, \xi}_k| < \lambda.$$
These conditions are a consequence of the requirement that the subgradient of the loss function contains 0 for a valid solution.

Note that the gradient of the active variables in \( M_j \) is unchanged if replacing \( \xi \in (\xi_j, \xi_{j+1}) \) by some \( \xi' \in (\xi_j, \xi_{j+1}) \) and replacing \( \hat{\beta}^{\lambda, \xi} \) by \( \hat{\beta}^{\lambda, \xi} + (\xi' - \xi)\hat{\theta}^{M_j} \). That is, for all \( k \in M_j \),

\[
(Y(\xi) - X\hat{\beta}^{\lambda, \xi})^T X_k = \{Y(\xi') - X(\hat{\beta}^{\lambda, \xi} + (\xi' - \xi)\hat{\theta}^{M_j})\}^T X_k,
\]
as the difference of both sides is equal to

\[
(\xi' - \xi)(\varepsilon - X\hat{\theta}^{M_j})^T X_k,
\]
and \((\varepsilon - X\hat{\theta}^{M_j})^T X_k = 0\) for all \( k \in M_j \), as \( \hat{\theta}^{M_j} \) is the OLS of \( \varepsilon \), regressed on the variables in \( M_j \). Equalities (35) and (36) are thus fulfilled for the solution and it remains to show that (37) also holds. For sufficiently small values of \( |\xi' - \xi| \), inequality (37) is clearly fulfilled for continuity reasons. Note that if \( |\xi' - \xi| \) is large enough such that for one variable \( k /\in M_j \) inequality (37) becomes an equality, then the set of active variables changes and thus either \( \xi' = \xi_{j+1} \) or \( \xi' = \xi_j \). We have thus shown that the solution \( \hat{\beta}^{\lambda, \xi} \) can for all \( \xi \in (\xi_j, \xi_{j+1}) \) be written as

\[
\hat{\beta}^{\lambda, \xi} = \hat{\beta}^{\lambda, \xi_j} + (\xi - \xi_j)\hat{\theta}^{M_j},
\]
which proves (34) and thus completes the proof. \( \square \)

**Lemma 6** Under the assumptions of Theorem 1, the variance term is bounded by

\[
\|\hat{\beta}^{\lambda} - \beta^{\lambda}\|_2 = O_p\left(\frac{\log p}{n} \frac{m_{\lambda_n}}{\sigma_y^2 \phi_{\min}(m_{\lambda_n})}\right),
\]
where \( m_{\lambda_n} = n^2 \lambda^{-2} \sigma_y^2 \phi_{\max}(\min\{n, p\}) \).
By Lemma 5 and 4, the variance can be bounded by
\[ \| \hat{\beta}_\lambda - \beta_\lambda \|_2^2 = O_p \left( \frac{\log p}{n} \frac{\tilde{m}}{\phi_{\min}(\tilde{m})} \right), \]
where \( \tilde{m} = \sup_{0 \leq \xi \leq 1} m^{\lambda, \xi} \) is the maximal number of active variable of the de-noised estimate (30). Using Lemma 3, the number \( \tilde{m} \) of active variables is bounded, with probability converging to 1 for \( n \to \infty \), by \( m_{\lambda_n} = n^2 \lambda_n^{-2} \sigma_y^2 \phi_{\max}(\min\{n, p\}) \), which completes the proof.

4. Proof of Theorem 2. The proof of Theorem 2 is in most parts analogous to the proof of Lemma 1 as the bound on the variance part remains unchanged. Only a bound on the \( \ell_2 \)-norm of the bias has to be recalculated. First, we derive a bound on the \( \ell_1 \)-norm of \( \gamma_\lambda \), similar to (17). The solution \( \beta_\lambda \) can be written as \( \beta + \gamma_\lambda \), where

\[ \gamma_\lambda = \arg\min_{\zeta \in \mathbb{R}^p} f(\zeta), \]

and the function \( f(\zeta) \) defined in (16) is now written as

\[ f(\zeta) = n\zeta^T C \zeta + \lambda \sum_{k \leq p} (|\beta_k + \zeta_k| - |\beta_k|). \]

In the proof of Lemma 1, \( K \) was the set of variables with truly non-zero coefficients. In the current setting, all coefficients are potentially different from zero. Let instead \( K \) be in the following the set of variables whose coefficient is among the \( r_n \) largest, where \( r_n \) is some sequence (to be chosen later) with \( r_n \to \infty \) for \( n \to \infty \). Assume without loss of generality that \( |\beta_1| \geq |\beta_2| \geq \ldots \geq |\beta_p| \). Then,

\[ K = \{ k : k \leq r_n \}. \]
We can use again that $f(\gamma) \leq 0$ as setting $\zeta = 0$ yields already the upper bound $f(0) = 0$. Using that $C$ is positive semi-definite,

$$
\sum_{k \in K^c} (|\beta_k + \gamma_k| - |\beta_k|) \leq - \sum_{k \in K} (|\beta_k + \gamma_k| - |\beta_k|).
$$

Note that on the one hand $|c + d| - |d| \leq |c|$ for all $c, d \in \mathbb{R}$. On the other hand, $|c + d| - |d| \geq |c| - 2|d|$ for all $c, d \in \mathbb{R}$. Thus

$$
\|\gamma(K^c)\|_{\ell_1} - 2\|\beta(K^c)\|_{\ell_1} = \sum_{k \in K^c} (|\gamma_k| - 2|\beta_k|) \leq \sum_{k \in K} |\gamma_k| = \|\gamma(K)\|_{\ell_1}.
$$

As $\beta$ lies in a weak $\ell_q$-ball with $0 < q < 1$, we have, by summing up the smallest entries of $\beta$ that there exists some constant $c > 0$ so that

$$
2\|\beta(K^c)\|_{\ell_1} \leq cs_{q,n} r_n^{(q-1)/q},
$$

and hence similarly as before

(39)

$$
\|\gamma\|_{\ell_1} = \|\gamma(K^c)\|_{\ell_1} + \|\gamma(K)\|_{\ell_1} \leq 2\|\gamma(K)\|_{\ell_1} + cs_{q,n} r_n^{(q-1)/q} \leq 2\sqrt{r_n}\|\gamma\|_{\ell_2} + cs_{q,n} r_n^{(q-1)/q},
$$

where the last inequality follows due to $\gamma(K)$ having at most $r_n$ non-zero entries, essentially by definition of $K$. Note that the last inequality holds for any sequence $r_n$. We are going to choose $r_n$ further below in a way that minimizes the bound on the bias.

Just as in the proof of Lemma 1, let $|\gamma(1)| \geq |\gamma(2)| \geq \ldots \geq |\gamma(p)|$ be the ordered entries of $\gamma$, let $u_n$ be some sequence for $n \to \infty$ and define $U = \{k : |\gamma_k| \leq |\gamma(u_n)|\}$. Analogously to the proof of Lemma 1, we obtain the bound (24) in slightly different notation as

(40)

$$
\gamma^T C \gamma \geq \phi_{\min}(u_n) \|\gamma\|_{\ell_2}^2 - 2\sqrt{\phi_{\max}(n) \phi_{\min}(u_n)} \|\gamma\|_{\ell_2} \|\gamma(U^c)\|_{\ell_2}.
$$
By the same argument as in the proof of Lemma 1, it also holds that $\gamma^T C \gamma \leq \lambda \|\gamma\|_{\ell_1}/n$. Just as in (25), we have additionally
\[
\|\gamma(U^c)\|_{\ell_2} \leq \|\gamma\|_{\ell_1}/\sqrt{u_n},
\]
and hence
\[
\lambda_n \|\gamma\|_{\ell_1}/n \geq \phi_{\text{min}}(u_n)\|\gamma\|_{\ell_2}^2 - 2\sqrt{\phi_{\text{max}}(n)\phi_{\text{min}}(u_n)}\|\gamma\|_{\ell_2}\|\gamma\|_{\ell_1}/\sqrt{u_n},
\]
which is equivalent to
\[
\phi_{\text{min}}(u_n)\|\gamma\|_{\ell_2}^2 \leq \|\gamma\|_{\ell_1} (\lambda_n/n + 2\sqrt{u_n^{-1} \phi_{\text{min}}(u_n) \phi_{\text{max}}(n)} \|\gamma\|_{\ell_2}).
\] (41)

We have still complete freedom in choosing the sequences $\{u_n\}_{n=1,\ldots,\infty}$ and $\{r_n\}_{n=1,\ldots,n}$. We now choose $u_n = m\lambda_n$, where $m\lambda_n$ is given in (8) with $m\lambda_n \sim n^2\lambda_n^{-2}$. By assumption, there exists some $\kappa > 0$ such that $\lim \inf_{n \to \infty} \phi_{\text{min}}(m\lambda_n) > \kappa$ and the last equation (41) implies thus that there exists a constant $c(\kappa) > 0$ so that for sufficiently large value of $n$,
\[
\|\gamma\|_{\ell_2}^2 \leq c(\kappa) \frac{\lambda_n}{n} \|\gamma\|_{\ell_1} (1 + \|\gamma\|_{\ell_2}).
\]
As long as we focus on cases for which $\|\gamma\|_{\ell_2}$ stays bounded (it will turn out below that this holds true), it follows that
\[
\|\gamma\|_{\ell_2}^2 = O\left(\frac{\lambda_n}{n} \|\gamma\|_{\ell_1}\right).
\]
Combing with the bound (39) on the $\ell_1$-norm of $\gamma$ then yields
\[
\|\gamma\|_{\ell_2}^2 = O\left(\frac{\lambda_n}{n} \sqrt{r_n} \|\gamma\|_{\ell_2} + \frac{\lambda_n}{n} s_{n,q,n} r_n^{(q-1)/q}\right).
\]
We can still choose $r_n$ freely. We choose $r_n$ to make both terms on the right hand side of the last equation of the same order. Using in particular
$r_n \propto (n s_{q,n}/\lambda_n)^q$, it follows with $m\lambda_n \asymp n^2/\lambda_n^2$ and the definition (12) of the effective sparsity as $s_{q,n}^{\text{eff}} = s_{q,n}^{2q/(2-q)}$ that

$$\|\gamma\|_{\ell_2}^2 = O\left\{ \frac{s_{q,n}^q}{m^{1-q/2}} \right\} = O\left\{ \left( \frac{s_{q,n}^{\text{eff}}}{m\lambda_n} \right)^{1-q/2} \right\},$$

which completes the proof.

5. Numerical Illustration: Frequency Detection. Instead of extensive numerical simulations, we would like to illustrate a few aspects of Lasso-type variable selection if the *irrepresentable condition* is not fulfilled. We are not making claims that the Lasso is superior to other methods for high-dimensional data. We merely want to draw attention to the fact that (a) the Lasso might not be able to select the correct variables but (b) comes nevertheless close to the true vector in an $\ell_2$-sense.

An illustrative example is frequency detection. It is of interest in some areas of the physical sciences to accurately detect and resolve frequency components; two examples are variable stars [26] and detection of gravitational waves [5, 29]. A non-parametric approach is often most suitable for fitting of the involved periodic functions [15]. However, we assume here for simplicity that the observations $Y = (Y_1, \ldots, Y_n)$ at time points $t = (t_1, \ldots, t_n)$ are of the form

$$Y_i = \sum_{\omega \in \Omega} \beta_\omega \sin(2\pi \omega t_i + \phi_\omega) + \varepsilon_i,$$

where $\Omega$ contains the set of fundamental frequencies involved, and $\varepsilon_i$ for $i = 1, \ldots, n$ is independently and identically distributed noise with $\varepsilon_i \sim \mathcal{N}(0, \sigma^2)$. To simplify the problem even more, we assume that the phases are known to be zero, $\phi_\omega = 0$ for all $\omega \in \Omega$. Otherwise one might like to
employ the Group Lasso [34], grouping together the sine and cosine part of identical frequencies.

It is of interest to resolve closely adjacent spectral lines [16] and we will work in this setting in the following. We choose for the experiment $n = 200$ evenly spaced observation times. There are supposed to be two closely adjacent frequencies with $\omega_1 = 0.0545$ and $\omega_2 = 0.0555 = \omega_1 + 1/300$, both entering with $\beta_{\omega_1} = \beta_{\omega_2} = 1$. As we have the information that the phase is zero for all frequencies, the predictor variables are given by all sine-functions with frequencies evenly spaced between $1/200$ and $1/2$, with a spacing of $1/600$ between adjacent frequencies.

In the chosen setting, the *irrepresentable condition* is violated for the frequency $\omega_m = (\omega_1 + \omega_2)/2$. Even in the absence of noise, this *resonance frequency* is included in the Lasso-estimate for all positive penalty parameters, as can be seen from the results further below. As a consequence of a violated *irrepresentable condition*, the largest peak in the periodgram is

\begin{figure}
\centering
\includegraphics[width=\textwidth]{fig1}
\caption{The energy $\log \Delta E(\omega)$ for a noise level $\sigma = 0.2$ is shown on the left for a range of frequencies $\omega$. A close-up of the region around the peak is shown on the right. The two frequencies $\omega_1$ and $\omega_2$ are marked with solid vertical lines, while the resonance frequency $(\omega_1 + \omega_2)/2$ is shown with a broken vertical line.}
\end{figure}
in general obtained for the resonance frequency. In Figure 1 we show the periodogram [27] under a moderate noise level $\sigma = 0.2$. The periodogram shows the amount of energy in each frequency, and is defined through the function

$$\Delta E(\omega) = \sum_i Y_i^2 - \sum_i (Y_i - \hat{Y}_i(\omega))^2,$$

where $\hat{Y}(\omega)$ is the least squares fit of the observations $Y$, using only sine and cosine functions with frequency $\omega$ as two predictor variables. There is clearly a peak at frequency $\omega_m$. As can be seen in the close-up around $\omega_m$, it is not immediately obvious from the periodogram that there are two frequencies at frequencies $\omega_1$ and $\omega_2$. As said above, the irrepresentable condition is violated for the resonance frequency and it is of interest to see which frequencies are picked up by the Lasso estimator.

The results are shown in Figures 2 and 3. Figure 3 highlights that the two true frequencies are with high probability picked up by the Lasso. The resonance frequency is also selected with high probability, no matter how the penalty is chosen. This result could be expected as the irrepresentable condition is violated and the estimator can thus not be sign consistent. We expect from the theoretical results in this manuscript that the coefficient of the falsely selected resonance frequency is very small if the penalty parameter is chosen correctly. And it can indeed be seen in Figure 2 that the coefficients of the true frequencies are much larger than the coefficient of the resonance frequency for an appropriate choice of the penalty parameter.

These results reinforce our conclusion that the Lasso might not be able to pick up the correct sparsity pattern, but delivers nevertheless useful approximations as falsely selected variables are chosen only with a very small
Fig 2. An example where the Lasso is bound to select wrong variables, while being a good approximation to the true vector in the $\ell_2$-sense. Top row: The noise level increases from left to right as $\sigma = 0, 0.1, 0.2, 1$. For one run of the simulation, paths of the estimated coefficients are shown as a function of the square root $\sqrt{\lambda}$ of the penalty parameter. The actually present signal frequencies $\omega_1$ and $\omega_2$ are shown as solid lines, the resonance frequency as a broken line, and all other frequencies are shown as dotted lines. Bottom row: the shaded areas contain, for 90% of all simulations, the regularization paths of the signal frequencies (region with solid borders), resonance frequency (area with broken borders) and all other frequencies (area with dotted boundaries). The path of the resonance frequency displays reverse shrinkage, as its coefficient gets in general smaller for smaller values of the penalty. As expected from the theoretical results, if the penalty parameter is chosen correctly, it is possible to separate the signal and resonance frequencies for sufficiently low noise levels by just retaining large and neglecting small coefficients. It is also apparent that the coefficient of the resonance frequency is small for a correct choice of the penalty parameter but very seldom identically zero.
Fig 3. The top row shows the $\ell_2$-distance between $\beta$ and $\hat{\beta}^\lambda$ separately for the signal frequencies (solid blue line), resonance frequency (broken red line) and all other frequencies (dotted gray line). It is evident that the distance is quite small for all three categories simultaneously if the noise level is sufficiently low (the noise level is again increasing from left to right as $\sigma = 0, 0.1, 0.2, 1$). The bottom row show on the other hand the average number of selected variables (with non-zero estimated regression coefficient) in each of the three categories as a function of the penalty parameter. It is impossible to choose the correct model, as the resonance frequency is always selected, no matter how low the noise level and no matter how the penalty parameter is chosen. This illustrates that sign consistency does not hold if the irrepresentable condition is violated, even though the estimate can be close to the true vector $\beta$ in the $\ell_2$-sense.
coefficient; this behavior is typical and expected from the results of Theorem 1. Falsely selected coefficients can thus be removed in a second step, either by thresholding variables with small coefficients or using other relaxation techniques. In any case, it is reassuring to know that all important variables are included in the Lasso estimate.

6. Concluding Remarks. It has recently been discovered that the Lasso cannot recover the correct sparsity pattern in certain circumstances, even not asymptotically for $p$ fixed and $n \to \infty$. This shed a little doubt on whether the Lasso is a good method for identification of sparse models for both low- and high-dimensional data.

Here we have shown that the Lasso can continue to deliver good approximations to sparse coefficient vectors $\beta$ in the sense that the $\ell_2$-difference $\|\beta - \hat{\beta}^\lambda\|_{\ell_2}$ vanishes for large sample sizes $n$, even if it fails to discover the correct sparsity pattern. The conditions needed for a good approximation the $\ell_2$-sense are weaker than the irrepresentable condition needed for sign consistency. We pointed out that the correct sparsity pattern could be recovered in a two-stage procedure. The first step consists in a regular Lasso fit. Variables with small absolute coefficient are then removed from the model in a second step.

We derived possible scenarios under which $\ell_2$-consistency can be achieved as a function of the sparsity of the vector $\beta$, the number of samples and the number of variables. The only condition on the design matrix we impose is that singular minimal eigenvalues of the design matrix induced by selecting a small number of variables are bounded away from zero by an arbitrarily small constant.
It was also shown that recovery of sparse vectors $\beta$ is possible if sparseness is measured in other ways than the number of non-zero entries of $\beta$. We obtain recovery of vectors in weak $\ell_q$-balls with $0 < q < 1$. In summary, the Lasso is selecting all sufficiently large coefficients, and possibly some other unwanted variables. The number of variables can thus be narrowed down considerably with the Lasso, while keeping all important variables. These results will hopefully support that the Lasso is a useful model identification method for high-dimensional data.
