\( \ell_2 \) subspace embedding in input-sparsity time

**Theorem ([Clarkson and Woodruff, STOC’13])**

Given a matrix \( A \in \mathbb{R}^{n \times d} \) with \( n \gg d \), let \( \Pi = SD \) where:
- \( D \in \mathbb{R}^{n \times n} \) is a diagonal matrix \( \{\pm 1\} \) entries u.a.r.
- \( S \in \mathbb{R}^{s \times n} \) has each column chosen independently and uniformly from the \( s \) standard basis vectors of \( \mathbb{R}^s \).

There is \( s = \mathcal{O}((d/\epsilon)^4 \log^2(d/\epsilon)) \) such that with a constant probability,

\[
(1 - \epsilon) \|Ax\|_2 \leq \|\Pi Ax\|_2 \leq (1 + \epsilon) \|Ax\|_2, \quad \forall x \in \mathbb{R}^d.
\]

\( \Pi A \) can be computed in \( \mathcal{O}(\text{nnz}(A)) \) time.

\[
\Pi = \begin{pmatrix}
1 & 1 & \cdots & 1 \\
1 & 1 & \cdots & 1 \\
\vdots & \ddots & \ddots & \vdots \\
1 & 1 & \cdots & 1
\end{pmatrix}
\begin{pmatrix}
\pm 1 & \pm 1 & \cdots & \pm 1 \\
\end{pmatrix}.
\]
CW proof of input-sparsity time $\ell_2$ embedding result

**Definition ($\ell_2$ leverage scores)**

Given any orthonormal basis $U$ for the range($A$) (where recall $A$ is of size $n \times d$ with $n \gg d$), the \( \ell_2 \) leverage scores of $A$ are the squared $\ell_2$ norms of $U$'s rows: $\|U(i)\|_2^2$, $i = 1, \ldots, n$.

Key idea: split rows of $A$ into “heavy hitters” and “light hitters” based on their $\ell_2$ leverage scores. Then show that:

- For high leverage score rows, the projection is an isometry.
- For low leverage score rows, use “a sparse Johnson-Lindenstrauss transform” of [DKS10].
- The cross-terms can be bounded separately.

Basic idea simple end elegant; actual proof long and detailed, using many ideas from TCS and streaming literature.
Simple proof of input-sparsity time $\ell_2$ embedding result

Key idea: view it as approximating matrix multiplication.

- Let $U$ be an orthonormal basis for range($A$); thus $U^T U = I_d$.
  Define $X = (\Pi U)^T (\Pi U) = U^T D^T S^T S D U$.
  Show that $U^T U \approx U^T D^T S^T S D U = (SDU)^T (SDU)$.

- By computing a few moments, it is easy to obtain that

\[
\mathbb{E}[\|X - I\|_F^2] = \frac{2}{s} \left( \sum_k (1 - \|U_k\|_4^4) + \sum_{k < l} (1 - 2\langle U_k^2, U_l^2 \rangle) \right) \leq \frac{d^2 + d}{s}
\]

- For any $\delta \in (0, 1)$, set $s = (d^2 + d)/(\epsilon^2 \delta)$. By Markov’s inequality,

\[
\Pr[\|X - I\|_F \geq \epsilon] = \Pr[\|X - I\|_F^2 \geq \epsilon^2] \leq \frac{d^2 + d}{\epsilon^2 s} = \delta.
\]

- Therefore, $\|X - I\|_2 \leq \|X - I\|_F \leq \epsilon$, w.p. $> 1 - \delta$, which implies

\[
(1 - \epsilon)\|Uz\|_2 \leq \|\Pi Uz\|_2 \leq (1 + \epsilon)\|Uz\|_2.
\]
Important point to remember

The embedding matrix $\Pi = SD$ does not preserve the norm of an arbitrary set of $e^d$ vectors.

- **JL proofs**: consider a fixed $x \in \mathbb{R}^d$; show that $\|\Pi x\|_2 = (1 \pm \epsilon)\|x\|_2$, w.p. $\geq 1 - 1/n^2$; and do a union bound to show all $\binom{n}{2}$ pairwise distances are preserved.

- **Subspace embedding proofs**: consider a fixed $x \in \mathbb{R}^d$; show that $\|\Pi x\|_2 = (1 \pm \epsilon)\|x\|_2$, w.p. $\geq 1 - e^{-d}$; put an $\epsilon$-net on the $d$-dimensional space; and do a union bound to show all pairwise distances are preserved.

The CW proof—explicitly, and the MM proof implicitly—critically exploits that the $e^d$ vectors come from a $d$-dimensional subspace of $\mathbb{R}^n$.

- have a very special structure—characterized by the leverage scores
- there can only be a small number of high-leverage components
Conditioning (for $\ell_1$ and $\ell_p$ regression)

**Definition ($\left(\alpha, \beta, p\right)$-conditioning (from DDHKM09))**

Given an $n \times d$ matrix $A$ and $p \in [1, \infty]$, let $q$ be the dual norm of $p$, and let $|A|_p^p = \sum_{ij} A_{ij}^p$. (Think $n \gg d$.) Then $A$ is ($\alpha, \beta, p$)-conditioned if:

- $|A|_p \leq \alpha$; and
- $\|z\|_q \leq \beta \|Az\|_p$, $\forall z \in \mathbb{R}^d$.

Let $\bar{\kappa}_p(A)$ be the minimum value of $\alpha \beta$ such that $A$ is ($\alpha, \beta, p$)-conditioned. A basis $U$ of range($A$) is a well-conditioned basis if $\kappa = \bar{\kappa}_p(U)$ is a low-degree polynomial in $d$, independent of $n$.

Special cases:

- $p = 2$: Orthonormal basis ($\alpha = d^{1/2}$ & $\beta = 1$, and can find “quickly”).
- $p = 1$: Auerbach basis ($\alpha = d$ & $\beta = 1$, “exists,” but can construct approximate bases with $\alpha = d^{3/2}$ & $\beta = 1$ “quickly.”)
Subspace-preserving sampling & approximate $\ell_p$ regression

Given a well-conditioned basis, we can do subspace-preserving sampling:

**Lemma (Fast Subspace-preserving Sampling [DDHKM09, CDMMMW13])**

Given a matrix $A \in \mathbb{R}^{n \times d}$, $p \in [1, \infty)$, $\epsilon > 0$, and a matrix $R \in \mathbb{R}^{d \times d}$ such that $AR^{-1}$ is well-conditioned. It takes $O(\text{nnz}(A) \cdot \log n)$ time to compute a sampling matrix $S \in \mathbb{R}^{s \times n}$ with $s = O(\tilde{\kappa}_p(AR^{-1})d|p/2-1|+1 \log(1/\epsilon)/\epsilon^2)$ such that with a constant probability,

$$(1 - \epsilon)\|Ax\|_p \leq \|SAx\|_p \leq (1 + \epsilon)\|Ax\|_p, \quad \forall x \in \mathbb{R}^d.$$ 

Given a subspace-preserving sampling algorithm, we can compute a $1 \pm \epsilon$ approximate solution to an $\ell_p$ regression problem:

**Lemma ($(1 \pm \epsilon)$-\(\ell_p\) Regression via Sampling [DDHKM09, CDMMMW13])**

Given an $\ell_p$ regression problem: \(\min_{x \in \mathbb{R}^d} \|Ax - b\|_p\).

Let $S$ be a $(1 \pm \epsilon)$-distortion embedding matrix of range([A | b]), and let $\hat{x} = \text{argmin}_{x \in \mathbb{R}^d} \|SAx - Sb\|_p$.

Then $\hat{x}$ is a $1 \pm \epsilon$-approximate solution to the original $\ell_p$ regression problem.
Low-distortion embeddings and regression problems

Succinct low-distortion embeddings and regression problems:

- Low-distortion $\ell_p$ subspace embeddings are the key building blocks for computing $(1 \pm \epsilon)$-approximation to an $\ell_p$ regression problem.
- (As a special case, for $p = 2$, this means finding, e.g., an orthogonal matrix from QR or SVD, or establishing a Johnson-Lindenstrauss result.)
- Given this embedding, we can get the solution to the $\ell_p$ regression problem in $O(nnz(A) \cdot \log n)$ additional time.
- For $p = 2$, this is actually only $O(nnz(A))$ additional time.

Many randomized matrix algorithms boil down to the $p = 2$ case.

But how long does it take to find a low-distortion embedding?

- Yang, Meng, and Mahoney 2013: quantile regression
- Etc.
Input-sparsity time algorithms for RandNLA problems

Comments on “input-sparsity time” algorithms:

- Actual running time is $O(\text{nnz}(A) + \text{poly}(d/\epsilon))$ time, where the second term is the time to solve the subproblem.
- So, running time is proportional to \text{nnz}(A) if $n \gg d$.
- Many tradeoffs, so can also get running times with leading terms of $O(\text{nnz}(A) \log(n))$ with better second-order terms.

More realistic models of data access:

- This is in the RAM model, idealized as $n \gg d$.
- Still open: some promising results in parallel/distributed environments, but not well-characterized theoretically.
- Still open: more realistic theoretical characterization of these ideas in more realistic data-access models, even on a single machine.
Onto $\ell_1$: $\ell_1$ subspace embedding in input-sparsity time

Replace $\{\pm 1\}$ random variables on diagonal of $D$ by Cauchy variables.

**Theorem**

Given a matrix $A \in \mathbb{R}^{n \times d}$ with $n \gg d$, let $\Pi = SC$ where:

- $C \in \mathbb{R}^{n \times n}$ is a diagonal matrix whose entries are i.i.d. samples from the Cauchy distribution,
- $S \in \mathbb{R}^{s \times n}$ has each column chosen independently and uniformly from the $s$ standard basis vectors of $\mathbb{R}^s$.

There is $s = O(d^5 \log^5 d)$ such that with a constant probability,

$$
\frac{\|Ax\|_1}{O(d^2 \log^2 d)} \leq \|\Pi Ax\|_1 \leq O(d \log d)\|Ax\|_1, \quad \forall x \in \mathbb{R}^d.
$$

In addition, $\Pi A$ can be computed in $O(\text{nnz}(A))$ time.

Cauchy variables used to approximate frequency moments (Indyk01), etc.
Sketch of proof: Auerbach basis matrix

Let the $n \times d$ matrix $U$ be an Auerbach basis matrix of $A_1$. By definition,

- $U$’s columns are unit vectors in the $\ell_1$ norm, thus $|U|_1 = d$,
- $\|x\|_\infty \leq \|Ux\|_1$, $\forall x \in \mathbb{R}^d$.

Things to note:

- This generalizes orthogonal matrices from $p = 2$.
- This generalizes to $p \in [1, \infty)$ [DDHKM09].
- This is a tool within the analysis—it must exist (it does!), but we do not need to compute it.

Definition ($\ell_1$ leverage scores (from CDMMMW13))

Given a well-conditioned basis $U$ for the range($A$) (where recall $A$ is of size $n \times d$ with $n \gg d$), the $\ell_1$ leverage scores of $A$ are the $\ell_1$ norms of $U$’s rows: $\|U_{(i)}\|_1$, $i = 1, \ldots, n$. 
Sketch of proof: Auerbach basis matrix

Then, it is sufficient to prove

\[ \|y\|_1/O(d^2 \log^2 d) \leq \|\Pi y\|_1 \leq O(d \log d)\|y\|_1, \quad \forall y \in Y, \]

where

\[ Y = \{ y \in \mathbb{R}^n \mid y = Ux, \|x\|_\infty = 1, x \in \mathbb{R}^d \}. \]

Notation:

- \( u_j \), the \( j \)-th row of \( U \), \( j = 1, \ldots, n \),
- \( v_j = \|u_j\|_1 \), \( j = 1, \ldots, n \), the \( \ell_1 \) leverage scores of \( A \).
Sketch of proof: stable distributions

- A distribution \( \mathcal{D} \) over \( \mathbb{R} \) is called \( p \)-stable, if for any \( m \) real numbers \( a_1, \ldots, a_m \), we have

\[
\sum_{i=1}^{m} a_i X_i \sim \left( \sum_{i=1}^{m} |a_i|^p \right)^{1/p} X,
\]

where \( X_i \overset{iid}{\sim} \mathcal{D} \) and \( X \sim \mathcal{D} \).

- Stable distributions exist for any \( p \in (0, 2] \) ([Lévy, 1952]).
  - The standard Gaussian distribution \( \mathcal{G} \) is 2-stable.
  - The standard Cauchy distribution \( \mathcal{C} \) is 1-stable.

- Denote by \( \mathcal{D}_p \) the “standard” \( p \)-stable distribution described by the characteristic function \( \varphi(t) = e^{-|t|^p} \).
Sketch of proof: Cauchy tail inequalities

Lemma (Cauchy upper tail inequality [CDMMMW13])

For \( i = 1, \ldots, m \), let \( C_i \) be \( m \) (not necessarily independent) standard Cauchy variables, and \( \gamma_i > 0 \) with \( \gamma = \sum_i \gamma_i \). Let \( X = \sum_i \gamma_i |C_i| \). For any \( t > 1 \),

\[
\Pr[X > t\gamma] \leq \frac{1}{\pi t} \left( \frac{\log(1 + (2mt)^2)}{1 - 1/(\pi t)} + 1 \right).
\]

Lemma (Cauchy lower tail inequality [CDMMMW13])

For \( i = 1, \ldots, m \), let \( C_i \) be independent standard Cauchy random variables, and \( \gamma_i \geq 0 \) with \( \gamma = \sum_i \gamma_i \). Let \( X = \sum_i \gamma_i |C_i| \). Then, for any \( t > 0 \),

\[
\log \Pr[X \leq (1 - t)\gamma] \leq \frac{-\gamma t^2}{3 \max_i \gamma_i}.
\]
Sketch of proof: upper bound

With a constant probability,

\[ |\Pi U|_1 = |SCU|_1 = \sum_{k=1}^{d} \sum_{i=1}^{s} \sum_{j=1}^{n} |s_{ij} c_j u_{jk}| \approx \sum_{k=1}^{d} \sum_{i=1}^{s} \sum_{j=1}^{n} (|s_{ij} u_{jk}|) |\tilde{c}_{ik}|, \]

where \( \{\tilde{c}_{ik}\} \) are dependent Cauchy random variables. Note that

\[ \sum_{k=1}^{d} \sum_{i=1}^{s} \sum_{j=1}^{n} |s_{ij} u_{jk}| = \sum_{k=1}^{d} \sum_{j=1}^{n} |u_{jk}| = |U|_1 = d. \]

Applying the upper tail inequality, we get, with probability at least 0.9,

\[ \|\Pi Ux\|_1 \leq |\Pi U|_1 \|x\|_\infty \leq |\Pi U|_1 \|Ux\|_1 \leq O(d \log d) \|Ux\|_1, \quad \forall x \in \mathbb{R}^d. \]
We partition indexes $[n]$ into two index sets: “heavy hitters” with large $\ell_1$ leverage scores; and “light hitters” with small $\ell_1$ leverage scores.

- $\tau = \omega^{1/4}/(d \log^2 d)$, where $\omega$ is a sufficiently large constant.
- Two index sets $H = \{j \mid v_j \geq \tau\}$ and $L = \{j \mid v_j < \tau\}$.
- When an index set appears as a superscript, we mean zeroing out elements or rows that do not belong to this index set.

It is easy to see that $|H| \leq \frac{d}{\tau}$ and $\|v^L\|_\infty \leq \tau$. 
Sketch of proof: lower bound when \( \|y^L\|_1 \geq \frac{1}{2} \|y\|_1 \)

Either \( \|y^L\|_1 \) or \( \|y^H\|_1 \) dominates \( \|y\|_1 \) because \( \|y\|_1 = \|y^L\|_1 + \|y^H\|_1 \).

Define:

- \( Y^H = \{ y \in Y | \|y^H\|_1 \geq \frac{1}{2} \|y\|_1 \} \),
- \( Y^L = Y \setminus Y^H = \{ y \in Y | \|y^L\|_1 > \frac{1}{2} \|y\|_1 \} \).

For any fixed \( y \in Y^L \), we can use the lower tail inequality to show that, with an exponentially small failure rate,

\[
\|\Pi y\|_1 \geq \frac{1}{4} \|y\|_1.
\]

Then by an \( \epsilon \)-net argument, we prove that, with probability at least 0.9, the following union bound holds:

\[
\|\Pi y\|_1 \geq \frac{1}{8} \|y\|_1, \quad \forall y \in Y^L.
\]
Sketch of proof: lower bound when $\|y^H\|_1 \geq \frac{1}{2}\|y\|_1$

Given $S$, define a mapping $\phi : \{1, \ldots, n\} \to \{1, \ldots, s\}$ such that $s_{\phi(j),j} = 1$, $j = 1, \ldots, n$. Let $\hat{L} = \{j \in L \mid \phi(j) \in \phi(H)\}$. For any $y \in Y^H$,

$$\|\Pi y\|_1 \geq \|\Pi(y^H + y^{\hat{L}})\|_1 \geq \|\Pi y^H\|_1 - \|\Pi U^{\hat{L}}\|_1$$

$$\geq \sum_{j \in H} |c_j| |y_j| - \|\Pi U^{\hat{L}}\|_1 \|x\|_\infty$$

$$\geq \left( \min_{j \in H} |c_j| \right) \|y^H\|_1 - \|\Pi U^{\hat{L}}\|_1.$$

The proof is done by showing that there exist constants $\omega_3$ and $\omega_4$ with $\omega_3 > 4\omega_4$ such that

- $\min_{j \in H} |c_j| > \omega_3/(d^2 \log^2 d)$ with probability at least 0.9,
- $\|\Pi U^{\hat{L}}\|_1 \leq \omega_4/(d^2 \log^2 d)$ with probability at least 0.9,
Onto $\ell_p$: Generalization to $\ell_p$ subspace embeddings

To generalize our $\ell_1$ result to $\ell_p$, we need to:

- prove tail inequalities for $p$-stable distributions by establishing an order among $p$-stable variables
- prove upper and lower tail inequalities for $p$-stable distributions
- easily generalize the rest of the analysis for $p = 1$

We can prove:

- Input-sparsity time low-distortion embedding for $\ell_p$
- Nearly-input-sparsity time solution to $\ell_p$ regression problems

Differences between our approach and CW’s:

- Our approach works for $p \in [1, 2)$ while CW’s works for all $p \in [1, \infty)$.
- CW doesn’t get the embedding in input-sparsity time.
- CW solves a rounding problem of size $n/\text{poly}(d) \times d$, while ours does not have this intermediate step.
What is quantile regression?

<table>

<td>$|Ax - b|_1$</td>
<td>$\rho_\tau(Ax - b)$</td>
</tr>
<tr>
<td>is a norm?</td>
<td>yes</td>
<td>yes</td>
<td>no</td>
</tr>
</tbody>
</table>

(Note, $\ell_1$ regression is a special case of quantile regression with $\tau = 0.5$.)
What is quantile regression?

- Quantile regression is a method to estimate the quantiles of the conditional distribution of response; it involves minimizing asymmetrically weighted absolute residuals:

  \[ \rho_\tau(z) = \begin{cases} \tau z, & z \geq 0; \\ (\tau - 1)z, & z < 0. \end{cases} \]

- Given \( A \in \mathbb{R}^{n \times d} \), \( b \in \mathbb{R}^n \), and a parameter \( \tau \in (0, 1) \), quantile regression problem can be solved via the optimization problem:

  \[ \minimize_{x \in \mathbb{R}^d} \rho_\tau(Ax - b), \quad (1) \]

  where \( \rho_\tau(y) = \sum_{i=1}^n \rho_\tau(y_i), \) for \( y \in \mathbb{R}^n \).

- We use \( A \) to denote \([A \quad -b]\), the quantile regression problem (1) can equivalently be expressed as the following,

  \[ \minimize_{x \in \mathcal{C}} \rho_\tau(Ax), \quad (2) \]

  where \( \mathcal{C} = \{x \in \mathbb{R}^d \mid c^T x = 1\} \) and \( c \) is a unit vector with the last coordinate 1.
Algorithms for quantile regression

Previous algorithms:

- Standard solver for quantile regression problem: an interior-point method \textit{ipm} [Portnoy and Koenker, 1997], which might be applicable for medium-large scale problem with size $1e6$ by 50.

- Best previous sampling algorithm for quantile regression problems, namely \textit{prqfn}, is using an interior-point method on a smaller problem that has been preprocessed by randomly sampling a subset of the data; see [Portnoy and Koenker, 1997].

Our approach:

- Conditioning: find an $\ell_1$-well-conditioned basis $U$ for the span of $A$.

- Leveraging: compute/estimate the $\ell_1$ leverage scores from the rows of $U$, and construct sampling matrix $S$ to draw a random sample.

- Solving the subproblem: minimize$_{x \in C} \rho_\tau(SAx)$. 
Conditioning: finding an $\ell_1$ well-conditioned basis

Recall, given an $n \times d$ matrix $A$ and $p \in [1, \infty]$, we want to find a low-distortion embedding $\Pi \in \mathbb{R}^{s \times n}$ s.t. $s = \mathcal{O}(\text{poly}(d))$ and

$$\frac{1}{\mathcal{O}(\text{poly}(d))} \cdot \|Ax\|_p \leq \|\Pi Ax\|_p \leq \mathcal{O}(\text{poly}(d)) \cdot \|Ax\|_p, \quad \forall x \in \mathbb{R}^d.$$ 

There are two main ways:

**Lemma (Conditioning via QR on low-distortion embedding)**

*Given a low-distortion embedding matrix $\Pi$ of $A_p$, let $R$ be the “$R$” matrix from the QR decomposition of $\Pi A$. Then, $AR^{-1}$ is $\ell_p$-well-conditioned.*

**Lemma (Conditioning via ellipsoidal rounding)**

*Given an $n \times d$ matrix $A$ and $p \in [1, \infty]$, it takes at most $\mathcal{O}(nd^3 \log n)$ time to find a matrix $R \in \mathbb{R}^{d \times d}$ such that $\kappa_p(AR^{-1}) \leq 2d.$*

**Table:** Summary of running time, condition number, and type of conditioning methods proposed recently. QR and ER refer, respectively, to methods based on the QR factorization and methods based on Ellipsoid Rounding.

**Definitions:**
- SC := Slow Cauchy Transform
- FC := Fast Cauchy Transform
- SPC := Sparse Cauchy Transform
Fast Randomized Algorithm for Quantile Regression

**Input:** $A \in \mathbb{R}^{n \times d}$ with full column rank, $\epsilon \in (0, 1/2)$, $\tau \in [1/2, 1)$.

**Output:** An approximate solution $\hat{x} \in \mathbb{R}^d$ to problem $\min_{x \in \mathcal{C}} \rho_\tau(Ax)$.

1. Compute $R \in \mathbb{R}^{d \times d}$ such that $AR^{-1}$ is a well-conditioned basis for range($A$).
2. Compute a $(1 \pm \epsilon)$-distortion subspace-preserving embedding $S \in \mathbb{R}^{s \times n}$.
3. Return $\hat{x} \in \mathbb{R}^d$ that minimizes $\rho_\tau(SAx)$ with respect to $x \in \mathcal{C}$.

**Theorem (Fast Quantile Regression)**

Given $A \in \mathbb{R}^{n \times d}$ and $\epsilon \in (0, 1/2)$, the above algorithm returns a vector $\hat{x}$ that, with probability at least 0.8, satisfies

$$\rho_\tau(A\hat{x}) \leq \left(\frac{1+\epsilon}{1-\epsilon}\right) \rho_\tau(Ax^*),$$

where $x^*$ is an optimal solution to the original problem. In addition, the algorithm to construct $\hat{x}$ runs in time

$$O(nnz(A) \cdot \log n) + \phi \left(O(\mu d^3 \log(\mu/\epsilon)/\epsilon^2), d\right),$$

where $\mu = \frac{\tau}{1-\tau}$ and $\phi(s, d)$ is the time to solve an $s \times d$ quantile regression problem.
Types of data considered

**Synthetic data**
Following the construction of CDMMMW13:

- Each row of the design matrix $A$ (size $\sim 10^6 \times 10^2$) is a canonical vector. Suppose the number of measurements on the $j$-th column are $c_j$, where $c_j = qc_{j-1}$, for $j = 2, \ldots, d$. Here $1 < q \leq 2$. $A$ is a $n \times d$ matrix.

- The true vector $x^*$ with length $d$ is a vector with independent Gaussian entries. Let $b^* = Ax^*$.

- The response vector $b$ is obtained by adding noise to $b^*$.

**Real data**
A data set consisting of a 5% sample of the U.S. 2000 Census data consisting of annual salary and related features. The size of the design matrix is $5 \times 10^6$ by 11.

“large” vs. “LARGE” data:
(These data are only “large,” but we also have implementations on “LARGE” data—embarrassingly parallel, so only 3 passes through the data in Hadoop.)
Relative error when the sampling size $s$ changes

Figure: First (solid lines) and third (dashed lines) quartiles of the relative errors of the objective value and solution vector. The test is on synthetic data with size 1e6 by 50.
Comparison of the running time of each conditioning method

The running time for each method

Figure: The running time for solving the problems associated with three different $\tau$ values when the sampling size $s$ changes.
Relative error when the higher dimension $n$ changes

\[ |f - f^*|/|f^*| \]

\[ \tau = 0.5, \quad \tau = 0.75, \quad \tau = 0.95 \]

\[ \frac{||x - x^*||_2}{||x^*||_2} \]

\[ \tau = 0.5, \quad \tau = 0.75, \quad \tau = 0.95 \]

Figure: The first (solid lines) and the third (dashed lines) quartiles of the relative errors of the objective value and solution vector, when $n$ varying from $1e4$ to $1e6$ and $d = 50$ by using SPC3.
Figure: The first (solid lines) and the third (dashed lines) quartiles of the relative errors of the objective value, and solution vector. The test data size 1e6 by 50.
Running time when the lower dimension $d$ changes

Figure: The running time for five methods for solving simulated problem, with $n = 1e6$, when $d$ varies.

Obvious/non-obvious extensions/improvements

- Extend input-sparsity ideas to get improved low-rank approximation of arbitrary $n \times d$ matrices $A$, with $n \approx d$ and rank parameter $k$.
  - The $1 \pm \epsilon$ input-sparsity time algorithm for $\ell_2$ regression implies $1 \pm \epsilon$ low-rank approximation for a weak (i.e., on the error w.r.t. only the top part of the spectrum) notion of approximation [DMM08,CW12].
  - Getting finer bounds (e.g., exactly $k$ columns, projecting onto $k + 10$ columns, etc.) requires finer control on how the top and bottom part of the spectrum interact (in the sketched space).
  - Genetics, astronomy, numerical, etc. applications/implementations of these ideas typically use these finer notions of low-rank approximation.

- Extend input-sparsity ideas to get good statistical properties, e.g., by exploiting sparsity tradeoffs of [NN12].

- Go beyond linear regression and extend input-sparsity ideas to, e.g., logistic regression and other convex optimization problems.

- Understand connections of input-sparsity ideas with SGD, coordinate descent, etc., at both “large” scale and “LARGE” scale.
Conclusion

- Extremely sparse random projection algorithms for least-squares, least absolute deviations, quantile, etc. regression problems that underlie many common matrix algorithms.
- Key step is constructing a succinct data representation that provides a low-distortion embedding.
- Run in input-sparsity or nearly-input-sparsity time (plus the time for solving a subproblem whose size depends only on the lower dimension of the input matrix) in an idealized theoretical model.
- Implementations in RAM (and parallel/distributed environments) perform well and illustrate tradeoffs, e.g., between running time to construct embedding and distortion quality of that embedding.
- Many interesting algorithmic/statistical questions (about both “large” and “LARGE” data) raised by these results...
