

0.1 Semidefinite Programming and Sum-of-Squares

In the previous subsection, we saw how to approximately solve $\max_{\|v\|_\infty \leq 1} v^\top \Sigma v$ via the semidefinite program defined by $\max_{M \succeq 0, \text{diag}(M)=1} \langle M, \Sigma \rangle$. In this section we will cover semidefinite programming in more detail, and build up to *sum-of-squares programming*, which will be used to achieve error $\mathcal{O}(\epsilon^{1-1/k})$ when p^* has “certifiably bounded” k th moments (recall that we earlier achieved error $\mathcal{O}(\epsilon^{1-1/k})$ for bounded k th moments but did not have an efficient algorithm).

A **semidefinite program** is an optimization problem of the form

$$\begin{aligned} & \text{maximize } \langle A, X \rangle \\ & \text{subject to } X \succeq 0, \\ & \quad \langle X, B_1 \rangle \leq c_1, \\ & \quad \vdots \\ & \quad \langle X, B_m \rangle \leq c_m. \end{aligned} \tag{1}$$

Here $\langle X, Y \rangle = \text{tr}(X^T Y) = \sum_{ij} X_{ij} Y_{ij}$ is the inner product between matrices, which is the same as the elementwise dot product when considered as n^2 -dimensional vectors.

Here the matrix A specifies the objective of the program, while (B_j, c_j) specify linear inequality constraints. We additionally have the positive semidefinite cone constraint that $X \succeq 0$, meaning that X must be symmetric with only non-negative eigenvalues. Each of A and B_1, \dots, B_m are $n \times n$ matrices while the c_j are scalars. We can equally well minimize as maximize by replacing A with $-A$.

While (1) is the canonical form for a semidefinite program, problems that are seemingly more complex can be reduced to this form. For one, we can add linear equality constraints as two-sided inequality constraints. In addition, we can replace $X \succeq 0$ with $\mathcal{L}(X) \succeq 0$ for any linear function \mathcal{L} , by using linear equality constraints to enforce the linear relations implied by \mathcal{L} . Finally, we can actually include any number of constraints $\mathcal{L}_1(X) \succeq 0, \mathcal{L}_k(X) \succeq 0$, since this is e.g. equivalent to the single constraint $\begin{bmatrix} \mathcal{L}_1(X) & 0 \\ 0 & \mathcal{L}_2(X) \end{bmatrix} \succeq 0$ when $k = 2$. As an example of these observations, the following (arbitrarily-chosen) optimization problem is also a semidefinite program:

$$\begin{aligned} & \underset{x, M, Y}{\text{minimize}} \quad a^\top x + \langle A_1, M \rangle + \langle A_2, Y \rangle \\ & \text{subject to } M + Y \succeq \Sigma \\ & \quad \text{diag}(M) = 1 \\ & \quad \text{tr}(Y) \leq 1 \\ & \quad Y \succeq 0 \\ & \quad \begin{bmatrix} 1 & x^\top \\ x & M \end{bmatrix} \succeq 0 \end{aligned} \tag{2}$$

(As a brief aside, the constraint $\begin{bmatrix} 1 & x^\top \\ x & M \end{bmatrix} \succeq 0$ is equivalent to $xx^\top \preceq M$ which is in turn equivalent to $x^\top M^{-1} x \leq 1$ and $M \succeq 0$.)

Semidefinite constraints as quadratic polynomials. An alternative way of viewing the constraint $M \succeq 0$ is that the polynomial $p_M(v) = v^\top M v$ is non-negative for all $v \in \mathbb{R}^d$. More generally, if we have a non-hogeneous polynomial $p_{M,y,c}(v) = v^\top M v + y^\top v + c$, we have $p_{M,y,c}(v) \geq 0$ for all v if and only if $M' \succeq 0$ for $M' = \begin{bmatrix} c & y^\top/2 \\ y/2 & M \end{bmatrix} \succeq 0$.

This polynomial perspective is helpful for solving eigenvalue-type problems. For instance, $\|M\| \leq \lambda$ if and only if $v^\top M v \leq \lambda \|v\|_2^2$ for all v , which is equivalent to asking that $v^\top (\lambda I - M)v \geq 0$ for all v . Thus $\|M\|$ can be expressed as the solution to

$$\begin{aligned} & \text{minimize } \lambda \\ & \text{subject to } \lambda I - M \succeq 0 \text{ (equivalently, } v^\top (\lambda I - M)v \geq 0 \text{ for all } v) \end{aligned} \tag{3}$$

We thus begin to see a relationship between moments and *polynomial non-negativity constraints*.

Higher-degree polynomials. It is tempting to generalize the polynomial approach to higher moments. For instance, $M_4(p)$ denote the 4th moment tensor of p , i.e. the unique symmetric tensor such that

$$\langle M_4, v^{\otimes 4} \rangle = \mathbb{E}_{x \sim p}[\langle x - \mu, v \rangle^4]. \tag{4}$$

Note we can equivalently express $\langle M_4, v^{\otimes 4} \rangle = \sum_{ijkl} (M_4)_{ijkl} v_i v_j v_k v_l$, and hence $(M_4)_{ijkl} = \mathbb{E}[(x_i - \mu)(x_j - \mu)(x_k - \mu)(x_l - \mu)]$.

A distribution p has bounded 4th moment if and only if $\langle M, v^{\otimes 4} \rangle \leq \lambda \|v\|_2^4$ for all v . Letting $p_M(v) \stackrel{\text{def}}{=} \langle M, v^{\otimes 4} \rangle$, we thus can express the 4th moment of p as the polynomial program

$$\begin{aligned} & \text{minimize } \lambda \\ & \text{subject to } \lambda(v_1^2 + \dots + v_d^2)^2 - p_M(v) \geq 0 \text{ for all } v \in \mathbb{R}^d \end{aligned} \tag{5}$$

Unfortunately, in contrast to (2), (5) is NP-hard to solve in general. We will next see a way to approximate (5) via a technique called *sum-of-squares programming*, which is a way of approximately reducing polynomial programs such as (5) to a large but polynomial-size semidefinite program.

Warm-up: certifying non-negativity over \mathbb{R} . Consider the one-dimensional polynomial

$$q(x) = 2x^4 + 2x^3 - x^2 + 5 \tag{6}$$

Is it the case that $q(x) \geq 0$ for all x ? If so, how would we check this?

What if I told you that we had

$$q(x) = \frac{1}{2}(2x^2 + x - 3)^2 + \frac{1}{2}(3x + 1)^2 \tag{7}$$

Then, it is immediate that $q(x) \geq 0$ for all x , since it is a (weighted) sum of squares.

How can we construct such decompositions of q ? First observe that we can re-write q as the matrix function

$$q(x) = \begin{bmatrix} 1 \\ x \\ x^2 \end{bmatrix}^\top \underbrace{\begin{bmatrix} 5 & 0 & 0 \\ 0 & -1 & 1 \\ 0 & 1 & 2 \end{bmatrix}}_M \begin{bmatrix} 1 \\ x \\ x^2 \end{bmatrix}. \tag{8}$$

On the other hand, the sum-of-squares decomposition for q implies that we can also write

$$q(x) = \begin{bmatrix} 1 \\ x \\ x^2 \end{bmatrix}^\top \left(\frac{1}{2} \begin{bmatrix} -3 \\ 1 \\ 2 \end{bmatrix} \begin{bmatrix} -3 \\ 1 \\ 2 \end{bmatrix}^\top + \frac{1}{2} \begin{bmatrix} 1 \\ 3 \\ 0 \end{bmatrix} \begin{bmatrix} 1 \\ 3 \\ 0 \end{bmatrix}^\top \right) \begin{bmatrix} 1 \\ x \\ x^2 \end{bmatrix}, \tag{9}$$

i.e. we can decompose the matrix M defining $q(x) = [1; x; x^2]^\top M [1; x; x^2]$ into a non-negative combination of rank-one outer products, which is true if and only if $M \succeq 0$.

There is one problem with this, which is that despite our successful decomposition of q , M is self-evidently not positive semidefinite! (For instance, $M_{22} = -1$.) The issue is that the matrix M defining $q(x)$ is not

unique. Indeed, any $M(a) = \begin{bmatrix} 5 & 0 & -a \\ 0 & 2a-1 & 1 \\ -a & 1 & 2 \end{bmatrix}$ would give rise to the same $q(x)$, and a sum-of-squares decomposition merely implies that $M(a) \succeq 0$ for *some* a . Thus, we obtain the following characterization:

$$q(x) \text{ is a sum of squares } \sum_{j=1}^k q_j(x)^2 \iff M(a) \succeq 0 \text{ for some } a \in \mathbb{R}. \quad (10)$$

For the particular decomposition above we took $a = 3$.

Sum-of-squares in two dimensions. We can generalize the insights to higher-dimensional problems. Suppose for instance that we wish to check whether $q(x, y) = a_{40}x^4 + a_{31}x^3y + a_{22}x^2y^2 + a_{13}xy^3 + a_{04}y^4 + a_{30}x^3 + a_{21}x^2y + a_{12}xy^2 + a_{03}y^3 + a_{20}x^2 + a_{11}xy + a_{02}y^2 + a_{10}x + a_{01}y + a_{00}$ is non-negative for all x, y . Again, this is hard-to-check, but we can hope to check the sufficient condition that q is a sum-of-squares, which we will express as $q \succeq_{\text{sos}} 0$. As before this is equivalent to checking that a certain matrix is positive semidefinite. Observe that

$$q(x, y) = \begin{bmatrix} x^2 \\ xy \\ y^2 \\ x \\ y \\ 1 \end{bmatrix}^\top \begin{bmatrix} a_{40} & a_{31}/2 & -b & a_{30}/2 & -c & -b' \\ a_{31}/2 & a_{22} + 2b & a_{13}/2 & a_{21}/2 + c & -c' & -c'' \\ -b & a_{13}/2 & a_{04} & a_{21}/2 + c' & a_{03}/2 & -b'' \\ a_{30}/2 & a_{21}/2 + c & a_{21}/2 + c' & a_{20} + 2b' & a_{11}/2 + c'' & a_{10}/2 \\ -c & -c' & a_{03}/2 & a_{11}/2 + c'' & a_{02} + 2b'' & a_{01}/2 \\ -b' & -c'' & -b'' & a_{10}/2 & a_{01}/2 & a_{00} \end{bmatrix} \begin{bmatrix} x^2 \\ xy \\ y^2 \\ x \\ y \\ 1 \end{bmatrix} \quad (11)$$

for any b, b', b'', c, c', c'' . Call the above expression $M(b, b', b'', c, c', c'')$, which is linear in each of its variables. Then we have $q \succeq_{\text{sos}} 0$ if and only if $M(b, b', b'', c, c', c'') \succeq 0$ for some setting of the b s and c s.

Sum-of-squares in arbitrary dimensions. In general, if we have a polynomial $q(x_1, \dots, x_d)$ in d variables, which has degree $2t$, then we can embed it as some matrix $M(b)$ (for decision variables b that capture the symmetries in M as above), and the dimensionality of M will be the number of monomials of degree at most t which turns out to be $\binom{d+t}{t} = \mathcal{O}((d+t)^t)$.

The upshot is that any constraint of the form $q \succeq_{\text{sos}} 0$, where q is linear in the decision variables, is a semidefinite constraint in disguise. Thus, we can solve any program of the form

$$\begin{aligned} & \underset{y}{\text{maximize}} \quad c^\top y \\ & \text{subject to } q_1 \succeq_{\text{sos}} 0, \dots, q_m \succeq_{\text{sos}} 0, \end{aligned} \quad (12)$$

where the q_j are linear in the decision variables y . (And we are free to throw in any additional linear inequality or semidefinite constraints as well.) We refer to such optimization problems as *sum-of-squares programs*, in analogy to semidefinite programs.

Sum-of-squares for k th moment. Return again to the k th moment problem. As a polynomial program we sought to minimize λ such that $\lambda(v_1^2 + \dots + v_d^2)^{k/2} - \langle M_{2k}, v^{\otimes 2k} \rangle$ was a non-negative polynomial. It is then natural to replace the non-negativity constraint with the constraint that $\lambda \|v\|_2^k - \langle M_{2k}, v^{\otimes 2k} \rangle \succeq_{\text{sos}} 0$. However, we actually have a bit more flexibility and it turns out that the best program to use is

$$\begin{aligned} & \text{minimize } \lambda \\ & \text{subject to } \lambda - \langle M_{2k}, v^{\otimes 2k} \rangle + (\|v\|_2^2 - 1)q(v) \succeq_{\text{sos}} 0 \text{ for some } q \text{ of degree at most } 2k - 2 \end{aligned} \quad (13)$$

Note that the family of all such q can be linearly parameterized and so the above is indeed a sum-of-squares program. It is always at least as good as the previous program because we can take $q(v) = \lambda(1 + \|v\|_2^2 + \dots + \|v\|_2^{2k-2})$.

When the solution λ^* to **(13)** is at most σ^{2k} for $M_{2k}(p)$, we say that p has $2k$ th moment *certifiably bounded* by σ^{2k} . In this case a variation on the filtering algorithm achieves error $\mathcal{O}(\sigma\epsilon^{1-1/2k})$. We will not discuss this in detail, but the main issue we need to resolve to obtain a filtering algorithm is to find some appropriate tensor T such that $\langle T, M_{2k} \rangle = \lambda^*$ and T “looks like” the expectation of $v^{\otimes 2k}$ for some probability distribution over the unit sphere. Then we can filter using $\tau_i = \langle T, (x_i - \hat{\mu})^{\otimes 2k} \rangle$.

To obtain T requires computing the dual of **(13)**, which requires more optimization theory than we have assumed from the reader, but it can be done in polynomial time. We refer to the corresponding T as a *pseudomoment* matrix. Speaking very roughly, T has all properties of a moment matrix that can be “proved using only sum-of-squares inequalities”, which includes all properties that we needed for the filtering algorithm to work. We will henceforth ignore the issue of T and focus on assumptions on p that ensure that $M_{2k}(p)$ is certifiably bounded. The main such assumption is the *Poincaré inequality*, which we cover in the next section.
