

## FAST MONTE CARLO ALGORITHMS FOR MATRICES I: APPROXIMATING MATRIX MULTIPLICATION\*

PETROS DRINEAS<sup>†</sup>, RAVI KANNAN<sup>‡</sup>, AND MICHAEL W. MAHONEY<sup>§</sup>

**Abstract.** Motivated by applications in which the data may be formulated as a matrix, we consider algorithms for several common linear algebra problems. These algorithms make more efficient use of computational resources, such as the computation time, random access memory (RAM), and the number of passes over the data, than do previously known algorithms for these problems. In this paper, we devise two algorithms for the matrix multiplication problem. Suppose  $A$  and  $B$  (which are  $m \times n$  and  $n \times p$ , respectively) are the two input matrices. In our main algorithm, we perform  $c$  independent trials, where in each trial we randomly sample an element of  $\{1, 2, \dots, n\}$  with an appropriate probability distribution  $\mathcal{P}$  on  $\{1, 2, \dots, n\}$ . We form an  $m \times c$  matrix  $C$  consisting of the sampled columns of  $A$ , each scaled appropriately, and we form a  $c \times n$  matrix  $R$  using the corresponding rows of  $B$ , again scaled appropriately. The choice of  $\mathcal{P}$  and the column and row scaling are crucial features of the algorithm. When these are chosen judiciously, we show that  $CR$  is a good approximation to  $AB$ . More precisely, we show that

$$\|AB - CR\|_F = O(\|A\|_F \|B\|_F / \sqrt{c}),$$

where  $\|\cdot\|_F$  denotes the Frobenius norm, i.e.,  $\|A\|_F^2 = \sum_{i,j} A_{ij}^2$ . This algorithm can be implemented without storing the matrices  $A$  and  $B$  in RAM, provided it can make two passes over the matrices stored in external memory and use  $O(c(m+n+p))$  additional RAM to construct  $C$  and  $R$ . We then present a second matrix multiplication algorithm which is similar in spirit to our main algorithm. In addition, we present a model (the pass-efficient model) in which the efficiency of these and other approximate matrix algorithms may be studied and which we argue is well suited to many applications involving massive data sets. In this model, the scarce computational resources are the number of passes over the data and the additional space and time required by the algorithm. The input matrices may be presented in any order of the entries (and not just row or column order), as is the case in many applications where, e.g., the data has been written in by multiple agents. In addition, the input matrices may be presented in a sparse representation, where only the nonzero entries are written.

**1. Introduction.** We are interested in developing and analyzing fast Monte Carlo algorithms for performing useful computations on large matrices. Examples of such computations include matrix multiplication, the computation of the singular value decomposition of a matrix, and the computation of compressed approximate decompositions of a matrix. In this paper, we present a computational model for computing on massive data sets (the pass-efficient model) in which our algorithms

may naturally be formulated; we also present two algorithms for the approximation of the product of two matrices. In a second paper we present two algorithms for the computation of low-rank approximations to a matrix [11]. Finally, in a third paper we present two algorithms to compute a compressed approximate decomposition to a matrix that has several appealing properties [12]. We expect our algorithms to be useful in many applications where data sets are modeled by matrices and are extremely large. For example, in information retrieval and data mining (two rapidly growing areas of research in computer science and scientific computation that build on techniques and theories from fields such as statistics, linear algebra, database theory, pattern recognition, and learning theory) a large collection of  $m$  objects, e.g., documents, genomes, images, or web pages, is implicitly presented as a set of points in an  $n$ -dimensional Euclidean space, where  $n$  is the number of features that describe the object. This collection may be represented by an  $m \times n$  matrix  $A$ , the rows of which are the object vectors and the columns of which are the feature vectors.

Recent interest in computing with massive data sets has led to the development of computational models in which the usual notions of time efficiency and space efficiency have been modified [23, 19, 3, 14, 10, 5]. In the applications that motivate these data-streaming models [19, 5], e.g., the observational sciences and the monitoring and operation of large networked systems, the data sets are much too large to fit into main memory. Thus, they are either not stored or are stored in a secondary storage device which may be read sequentially as a data stream but for which random access is very expensive. Typically, algorithms that compute on a data stream examine the data stream, keep a small “sketch” of the data, and perform computations on the sketch. Thus, these algorithms are usually randomized and approximate, and their performance is evaluated by considering resources such as the time to process an item in the data stream, the number of passes over the data, the additional workspace and additional time required, and the quality of the approximations returned. (Note that in some cases the term “data-streaming model” refers to a model in which only a single pass over the data is allowed [19, 5].)

The motivation for our particular “pass-efficient” approach is that in modern computers the amount of external memory (e.g., disk storage or tape storage) has increased enormously, while RAM and computing speeds have increased, but at a substantially slower pace. Thus, we have the ability to store large amounts of data, but not in RAM, and we do not have the computational ability to process these data with algorithms that require superlinear time. A related motivation is that input-output rates have not increased proportionally. Thus, the size of the data inputs (as limited, e.g., by the size of disks) has increased substantially faster than the rate at which we can access the data randomly.

In order to provide a framework in which to view the algorithms presented herein, we first introduce and describe the pass-efficient model of data-streaming computation [10]. In the pass-efficient model the computational resources are the number of sequential-access passes over the data and the additional RAM space and the additional time required. Thus, our algorithms are quite different from traditional numerical analysis approaches and generally fit within the following framework. Our algorithms will be allowed to read the matrices from external storage a few—e.g., one or two or three—times and keep a small randomly chosen and rapidly computable “sketch” of the matrices in RAM. Our algorithms will also be permitted additional RAM space and additional time in order to perform computations on the “sketch.” The results of these computations will be returned as approximations to the solution of the original problem.

In all of our algorithms, an important implementation issue will be how to form the random sample. An obvious choice is to use uniform sampling, where each data object is equally likely to be picked. Uniform sampling can be performed blindly, in which case the sample to be chosen can be decided before seeing the data. Even when the number of data elements is not known in advance an element can be selected uniformly at random in one pass over the data; see Lemma 1. Uniform sampling fits within our framework and is useful for certain (restricted) classes of problems. To obtain much more generality, we will sample according to a judiciously chosen (and data-dependent) set of nonuniform sampling probabilities. This nonuniform sampling, in which in the first pass through the data we compute sampling probabilities (e.g., we may keep rows or columns of a data matrix with probability proportional to the square of their lengths) and in the second pass we draw the sample, offers substantial gains. For example, it allows us to approximately solve problems in sparse matrices as well as dense matrices.

The idea of sampling rows or columns of matrices in order to approximate various operations is not new; indeed, a motivation for our main matrix multiplication algorithm came from [15]. In this paper and accompanying work [11, 12], we extend those ideas and develop algorithms with provable error bounds for a variety of matrix operations. One of the main contributions of our work is to demonstrate that a “sketch” consisting of a small judiciously chosen random sample of rows and/or columns of the input matrix or matrices is adequate for provably rapid and efficient approximation of several common matrix operations. We believe that the underlying principle of using nonuniform sampling to create “sketches” of the data in a small number of passes (and “pass-efficient” approaches more generally) constitutes an appealing and fruitful direction for algorithmic research in order to address the size and nature of modern data sets.

In the present paper, we present two simple and intuitive algorithms which, when given an  $m \times n$  matrix  $A$  and an  $n \times p$  matrix  $B$ , compute an approximation to the product  $AB$ . In the first algorithm, the BASICMATRIXMULTIPLICATION algorithm of section 4, we perform  $c$  independent trials, where in each trial we randomly sample an element of  $\{1, 2, \dots, n\}$  with an appropriate probability distribution  $\mathcal{P}$  on  $\{1, 2, \dots, n\}$ . We form an  $m \times c$  matrix  $C$  consisting of the sampled columns of  $A$ , each scaled appropriately, and we form a  $c \times n$  matrix  $R$  using the corresponding rows of  $B$ , again scaled appropriately. The choice of  $\mathcal{P}$  and the column and row scaling are crucial features of the algorithm. When these are chosen judiciously, we show that  $CR$  is a good approximation to  $AB$ . More precisely, we show that

$$\|AB - CR\|_F = O(\|A\|_F \|B\|_F / \sqrt{c}),$$

where  $\|\cdot\|_F$  denotes the Frobenius norm, i.e.,  $\|A\|_F^2 = \sum_{i,j} A_{ij}^2$ , holds in expectation and with high probability. Thus, in particular, when  $B = A^T$  we have that if  $c = \Omega(1/\epsilon^2)$ , then  $\|AA^T - CC^T\|_F \leq \epsilon \|A\|_F^2$  holds with high probability. This algorithm can be implemented without storing the matrices  $A$  and  $B$  in RAM, provided it can make two passes over the matrices stored in external memory and use  $O(c(m+n+p))$  additional RAM; thus it will be efficient in the pass-efficient model.

In the second algorithm, the ELEMENTWISEMATRIXMULTIPLICATION algorithm of section 5, which is an extension of ideas from [2, 1], elements of  $A$  and  $B$ , rather than columns and rows, are randomly either zeroed out or kept and rescaled, thereby constructing matrices  $\tilde{A}$  and  $\tilde{B}$ . Although this algorithm lacks a useful bound on

$\|AB - \tilde{A}\tilde{B}\|_F$ , under appropriate assumptions a bound on the spectral norm of the form

$$\|AB - \tilde{A}\tilde{B}\|_2 = O(\|A\|_F \|B\|_F / \sqrt{c})$$

holds with high probability.

After this introduction, we provide in section 2 a review of the relevant linear algebra, and in section 3 we introduce the pass-efficient model of data-streaming computation and discuss several technical sampling lemmas. In section 4 we introduce and analyze in detail the BASICMATRIXMULTIPLICATION algorithm to approximate the product of two matrices. Then, in section 5 we describe and analyze the ELEMENTWISEMATRIXMULTIPLICATION algorithm which is based on the ideas of [2, 1]. Finally, in section 6 we provide a discussion and conclusion. In the appendix, we provide further analysis of the BASICMATRIXMULTIPLICATION algorithm.

**2. Review of linear algebra.** This section contains a review of some linear algebra that will be useful throughout the paper. For more detail, see [18, 20, 25, 6] and the references therein.

For a vector  $x \in \mathbb{R}^n$  we let  $|x| = (\sum_{i=1}^n |x_i|^2)^{1/2}$  denote its Euclidean length. For a matrix  $A \in \mathbb{R}^{m \times n}$  we let  $A^{(j)}$ ,  $j = 1, \dots, n$ , denote the  $j$ th column of  $A$  as a column vector and  $A_{(i)}$ ,  $i = 1, \dots, m$ , denote the  $i$ th row of  $A$  as a row vector. We denote matrix norms by  $\|A\|_\xi$ , using subscripts to distinguish between various norms. Of particular interest will be the Frobenius norm which is defined by

$$(1) \quad \|A\|_F = \sqrt{\sum_{i=1}^m \sum_{j=1}^n A_{ij}^2},$$

and the spectral norm which is defined by

$$(2) \quad \|A\|_2 = \sup_{x \in \mathbb{R}^n, x \neq 0} \frac{|Ax|}{|x|}.$$

These norms are related to each other as  $\|A\|_2 \leq \|A\|_F \leq \sqrt{n} \|A\|_2$ .

**3. The pass-efficient model and sampling lemmas.** In this section, we informally define a computational model in which the computational resources are the number of passes over the data and the additional space and additional time required. In addition, we present several technical sampling lemmas.

**3.1. The pass-efficient model.** The pass-efficient model of data-streaming computation is a model that is motivated by the observation that in modern computers the amount of disk storage, i.e., sequential access memory, has increased very rapidly while random access memory (RAM) and computing speeds have increased at a substantially slower pace [10]. Thus, one has the ability to store very large amounts of data but does not have random access to the data. Additionally, processing the data with algorithms that take low polynomial time or linear time with large constants is prohibitive.

To model this phenomenon, we consider the pass-efficient model, in which the three computational resources of interest are the number of passes over the data and the additional space and time required [10]. The data are assumed to be stored in an external disk space, to consist of elements whose size is bounded by a constant, and to be presented to an algorithm on a read-only tape. The only access an algorithm has

to the data is via a pass, where a *pass* over the data is a sequential read of the entire input from disk where only a constant amount of processing time is permitted per bit read. Note that this is a more restrictive notion of a pass over the data than in other data-streaming models [23, 19, 14]; in particular, in the pass-efficient model only a constant rather than a logarithmic (in the data input length) amount of computation is permitted per bit read. In addition to the external disk space to store the data and to a small number of passes over the data, an algorithm in the pass-efficient model is permitted to use *additional RAM space* and *additional computation time*. An algorithm operating in this model is considered *pass-efficient* if it requires a fixed number of passes, independent of the input size, and additional space and time which are sublinear in the length of the data stream in order to compute a “description” of the solution, which is then returned by the algorithm. A *description* of the solution is either an explicit solution (if that is possible within the specified additional space and time) or an implicit representation of the solution that can be computed in the allotted additional space and time, and that can be expanded into an explicit solution with the additional expense of one pass over the data and linear (in the data input length) additional space and time. Note that, depending on the application, this last step may or may not be necessary. Note also that if the data are represented by an  $m \times n$  matrix, then the data stream has length  $O(mn)$  and an algorithm which uses additional space and time that is linear in the number of data points or in the dimensionality of the data points, i.e., that is  $O(m)$  or  $O(n)$ , is sublinear in the length of the data stream and thus is pass-efficient. We will be primarily interested in models that require additional space and time that is either  $O(m+n)$  or constant with respect to  $m$  and  $n$ .

The *sparse-unordered representation* of data is a form of data representation in which each element of the data stream consists of a pair  $((i, j), A_{ij})$  where the elements in the data stream may be unordered with respect to the indices  $(i, j)$ , and only the nonzero elements of the matrix  $A$  need to be presented. This very general form is suited to applications where, e.g., multiple agents may write parts of a matrix to a central database and where one cannot make assumptions about the rules for write-conflict resolution. The data stream read by algorithms in the pass-efficient model is assumed to be presented in the *sparse-unordered representation*. Other related methods of data representation have been studied within the data-streaming context; see, e.g., [17] for applications to the problem of dynamic histogram maintenance.

**3.2. Sampling lemmas.** In this section we present two sampling primitives that will be used by our algorithms. Consider the SELECT algorithm presented in Figure 1. The following lemma establishes that in one pass over the data one can sample an element according to certain probability distributions.

LEMMA 1. *Suppose that  $\{a_1, \dots, a_n\}$ ,  $a_i \geq 0$ , are read in one pass, i.e., one sequential read over the data, by the SELECT algorithm. Then the SELECT algorithm requires  $O(1)$ , i.e., constant with respect to  $n$ , additional storage space and returns a random  $i^*$  sampled from the probability distribution  $\Pr[i^* = i] = a_i / \sum_{i'=1}^n a_{i'}$ .*

*Proof.* First, note that retaining the selected value and the running sum requires  $O(1)$  additional space. The remainder of the proof is by induction. After reading the first element  $a_1$ ,  $i^* = 1$  with probability  $a_1/a_1 = 1$ . Let  $D_\ell = \sum_{i'=1}^\ell a_{i'}$  and suppose that the algorithm has read  $a_1, \dots, a_\ell$  thus far and has retained the running sum  $D_\ell$  and a sample  $i^*$  such that  $\Pr[i^* = i] = a_i/D_\ell$ . Upon reading  $a_{\ell+1}$  the algorithm lets  $i^* = \ell + 1$  with probability  $a_{\ell+1}/D_{\ell+1}$  and retains  $i^*$  at its previous value otherwise. At that point, clearly  $\Pr[i^* = \ell + 1] = a_{\ell+1}/D_{\ell+1}$ ; furthermore for

SELECT Algorithm.

**Input:**  $\{a_1, \dots, a_n\}$ ,  $a_i \geq 0$ , read in one pass, i.e., one sequential read, over the data.

**Output:**  $i^*, a_{i^*}$ .

1.  $D = 0$ .
2. For  $i = 1$  to  $n$ ,
  - (a)  $D = D + a_i$ .
  - (b) With probability  $a_i/D$ , let  $i^* = i$  and  $a_{i^*} = a_i$ .
3. Return  $i^*, a_{i^*}$ .

FIG. 1. The SELECT algorithm.

$i = 1, \dots, \ell$ ,  $\Pr[i^* = i] = \frac{a_i}{D_\ell} \left(1 - \frac{a_{\ell+1}}{D_{\ell+1}}\right) = \frac{a_i}{D_{\ell+1}}$ . By induction this result holds when  $\ell + 1 = n$  and the lemma follows.  $\square$

In a single pass over the data this algorithm can be run in parallel with  $O(s)$  total memory units to return  $s$  independent samples  $i_1^*, \dots, i_s^*$  such that for each  $i_t^*$ ,  $t = 1, \dots, s$ , we have  $\Pr[i_t^* = i] = a_i / \sum_{i'=1}^n a_{i'}$ .

The next lemma is a modification of the previous lemma to deal with the case where a matrix is read in the sparse-unordered representation and one wants to choose a row label with a certain probability. This can also be implemented in  $O(1)$  additional space and time. Note that a trivial modification would permit choosing a column label.

**LEMMA 2.** *Suppose that  $A \in \mathbb{R}^{m \times n}$  is presented in the sparse-unordered representation and is read in one pass, i.e., one sequential read over the data, by the SELECT algorithm. Then the algorithm requires  $O(1)$ , i.e., constant with respect to  $m$  and  $n$ , additional storage space and returns  $i^*, j^*$  such that  $\Pr[i^* = i \wedge j^* = j] = A_{ij}^2 / \|A\|_F^2$  and thus  $\Pr[i^* = i] = |A_{(i)}|^2 / \|A\|_F^2$ .*

*Proof.* Since  $A_{i^*j^*}^2 > 0$  the first claim follows from Lemma 1; the second follows since

$$\Pr[i^* = i] = \sum_{j=1}^n \Pr[i^* = i \wedge j^* = j] = \sum_{j=1}^n \frac{A_{ij}^2}{\|A\|_F^2} = \frac{|A_{(i)}|^2}{\|A\|_F^2}. \quad \square$$

Algorithms such as the SELECT algorithm, which select elements from a large pool of elements whose size is initially unknown, have been called reservoir algorithms [28].

**4. The basic matrix multiplication approximation algorithm.** In this section, which describes the main result of the paper, the BASICMATRIXMULTIPLICATION algorithm to approximate the product of two matrices is presented; it is analyzed in this section and in the appendix. After describing the algorithm in section 4.1 we describe its implementation and running time issues in section 4.2. In section 4.3 we analyze the algorithm and provide error bounds for arbitrary probability distributions; in section 4.4 error bounds are derived for probability distributions which are nearly optimal in a well-defined sense. We provide further discussion of the algorithm in section 6, and in the appendix we provide further analysis of the BASICMATRIXMULTIPLICATION algorithm.

BASICMATRIXMULTIPLICATION Algorithm.

**Input:**  $A \in \mathbb{R}^{m \times n}$ ,  $B \in \mathbb{R}^{n \times p}$ ,  $c \in \mathbb{Z}^+$  such that  $1 \leq c \leq n$ , and  $\{p_i\}_{i=1}^n$  such that  $p_i \geq 0$  and  $\sum_{i=1}^n p_i = 1$ .

**Output:**  $C \in \mathbb{R}^{m \times c}$  and  $R \in \mathbb{R}^{c \times p}$ .

1. For  $t = 1$  to  $c$ ,
  - (a) Pick  $i_t \in \{1, \dots, n\}$  with  $\Pr[i_t = k] = p_k$ ,  $k = 1, \dots, n$ , independently and with replacement.
  - (b) Set  $C^{(t)} = A^{(i_t)}/\sqrt{cp_{i_t}}$  and  $R_{(t)} = B_{(i_t)}/\sqrt{cp_{i_t}}$ .
2. Return  $C, R$ .

FIG. 2. The BASICMATRIXMULTIPLICATION algorithm.

**4.1. The algorithm.** Recall that for  $A \in \mathbb{R}^{m \times n}$  and  $B \in \mathbb{R}^{n \times p}$ , the product  $AB$  may be written as the sum of  $n$  rank-one matrices

$$(3) \quad AB = \sum_{t=1}^n A^{(t)} B_{(t)}.$$

When matrix multiplication is formulated in this manner, a simple randomized algorithm to approximate the product matrix  $AB$  suggests itself: randomly sample with replacement from the terms in the summation  $c$  times according to a probability distribution  $\{p_i\}_{i=1}^n$ , scale each term in an appropriate manner, and output the sum of the scaled terms. If  $m = p = 1$ , then  $A^{(t)}, B_{(t)} \in \mathbb{R}$  and it is straightforward to show that this sampling procedure produces an unbiased estimator for the sum. When the terms in the sum are rank-one matrices, as in (3), we show that similar results hold.

Consider the BASICMATRIXMULTIPLICATION algorithm described in Figure 2. When this algorithm is given as input two matrices  $A$  and  $B$ , a probability distribution  $\{p_i\}_{i=1}^n$ , and a number  $c$  of column-row pairs to choose, it returns as output matrices  $C$  and  $R$  such that the product  $CR$  is an approximation to  $AB$ . Observe that since

$$CR = \sum_{t=1}^c C^{(t)} R_{(t)} = \sum_{t=1}^c \frac{1}{cp_{i_t}} A^{(i_t)} B_{(i_t)}$$

the procedure for sampling and scaling column and row pairs that is used in the BASICMATRIXMULTIPLICATION algorithm corresponds to sampling terms in (3) and rescaling by dividing by  $cp_{i_t}$  if the  $t$ th term is sampled. Alternatively, one could define the sampling matrix  $S \in \mathbb{R}^{n \times c}$  to be the zero-one matrix where  $S_{ij} = 1$  if the  $i$ th column of  $A$  (and thus also the  $i$ th row of  $B$ ) is chosen in the  $j$ th independent random trial, and  $S_{ij} = 0$  otherwise. If the rescaling matrix  $D \in \mathbb{R}^{c \times c}$  is the diagonal matrix with  $D_{tt} = 1/\sqrt{cp_{i_t}}$ , then

$$C = ASD \quad \text{and} \quad R = (SD)^T B$$

so that  $CR = ASD(SD)^T B \approx AB$ . Figure 3 presents a diagram illustrating the action of the BASICMATRIXMULTIPLICATION algorithm. The product  $AB$  is shown as  $B$  and then  $A$  operating between the high-dimensional  $\mathbb{R}^p$  and  $\mathbb{R}^m$  via the high-dimensional  $\mathbb{R}^n$ ; this is approximated by  $CR$ , which is shown as  $R$  and then  $C$  operating between  $\mathbb{R}^p$  and  $\mathbb{R}^m$  via the low-dimensional subspace  $\mathbb{R}^c$ . Also shown are the sampling matrix  $S$  and the diagonal rescaling matrix  $D$ .

FIG. 3. *Diagram for the BASICMATRIXMULTIPLICATION algorithm.*

An important issue is the choice of the probabilities  $\{p_i\}_{i=1}^n$  and the scaling. It is easily seen that the scaling of  $1/\sqrt{cp_i}$  used in the BASICMATRIXMULTIPLICATION algorithm makes  $CR$  an unbiased estimator of  $AB$ ; see Lemma 3. Lemma 3 also computes  $\mathbf{Var}[(CR)_{ij}]$  under general probabilities  $\{p_i\}_{i=1}^n$ . We then compute  $\mathbf{E}[\|AB - CR\|_F^2]$  and see that probabilities of the form  $p_k = |A^{(k)}||B_{(k)}|/N$ ,  $k = 1, \dots, n$ , where  $N$  is a normalization, are optimal in that they minimize this quantity; see Lemma 4.

This approach for approximating matrix multiplication has several advantages. First, it is conceptually simple, and in some cases it can be generalized to approximate the product of more than two matrices; see section A.1 for more on the latter point. Second, since the heart of the algorithm involves matrix multiplication of smaller matrices, it can use any algorithm in the literature for performing the desired matrix multiplication [18, 26, 8]. Third, this approach does not tamper with the sparsity of the matrices, unlike an algorithm that would project both  $A$  and  $B$  to the same random  $c$ -dimensional subspace and take the product of the projections. Finally, the algorithm can be easily implemented; see sections 4.2 and 6 for more discussion.

**4.2. Implementation of the sampling and running time.** To implement the BASICMATRIXMULTIPLICATION algorithm, it must be decided which elements of the input to sample and those elements must then be sampled. In the case of uniform sampling one can decide before the input is seen which column-row pairs to sample. Then, a single pass over the matrices is sufficient to sample the columns and rows of interest and to construct  $C$  and  $R$ ; this requires  $O(c(m+p))$  additional time and space. We will see below that it is useful to sample according to a nonuniform probability distribution that depends on column and row lengths, e.g., see (5) and (7). In order to decide which column-row pairs to sample in such a case, one pass through the matrices and  $O(n)$  additional time and space is sufficient; in the additional space running totals of  $|A^{(k)}|^2$  and  $|B_{(k)}|^2$  are kept, so that after the first pass  $|A^{(k)}|$ ,  $|B_{(k)}|$ ,  $k = 1, \dots, n$ , and thus the probabilities, can be calculated in  $O(n)$  additional time. Then in a second pass the columns and rows of interest can be sampled and  $C$  and  $R$  can be constructed and stored; this requires  $O(c(m+p))$  additional space and time. Thus, in addition to either one or two passes over the data, for both uniform and nonuniform sampling,  $O(c(m+n+p))$  additional space and time is sufficient to sample from the matrices  $A$  and  $B$  of the input and to construct the matrices  $C$  and  $R$ .

If  $B = A^T$  and nonuniform sampling is performed (assuming probabilities of the form (5) or (7)), the resource requirements are slightly different. Due to Lemma 2 we can select which columns of  $A$  to choose using constant (with respect to  $n$ ) additional

space and time during the first pass. Then, during the second pass, these columns may be extracted and the matrices  $C$  and  $R = C^T$  may be constructed using  $O(cm)$  additional space and time; this will be used in the LINEARTIMESVD algorithm of [11]. Note that if only a constant-sized part of the columns of  $C$  is needed, as, for example, in the CONSTANTTIMESVD algorithm of [11], then extracting and storing this constant-sized subset of the samples desired may be performed using constant additional space and time.

**4.3. Analysis of the algorithm for arbitrary probabilities.** In this section we prove upper bounds for  $\|AB - CR\|_F^2$ , where  $C$  and  $R$  are returned from the BASICMATRIXMULTIPLICATION algorithm. Recall that by Jensen's inequality bounding  $\|AB - CR\|_F^2$  (in expectation) implies a bound for  $\|AB - CR\|_F$ . Recall also that a bound on  $\|AB - CR\|_F$  immediately provides a bound on  $\|AB - CR\|_2$  since  $\|AB - CR\|_2 \leq \|AB - CR\|_F$ .

Our first lemma proves that the expectation of the  $(i, j)$ th element of the approximation is equal to the  $(i, j)$ th element of the exact product; it also describes the variance of the approximation of the  $(i, j)$ th element.

LEMMA 3. *Suppose  $A \in \mathbb{R}^{m \times n}$ ,  $B \in \mathbb{R}^{n \times p}$ ,  $c \in \mathbb{Z}^+$  such that  $1 \leq c \leq n$ , and  $\{p_i\}_{i=1}^n$  are such that  $p_i \geq 0$  and  $\sum_{i=1}^n p_i = 1$ . Construct  $C$  and  $R$  with the BASICMATRIXMULTIPLICATION algorithm, and let  $CR$  be an approximation to  $AB$ . Then*

$$\mathbf{E}[(CR)_{ij}] = (AB)_{ij}$$

and

$$\mathbf{Var}[(CR)_{ij}] = \frac{1}{c} \sum_{k=1}^n \frac{A_{ik}^2 B_{kj}^2}{p_k} - \frac{1}{c} (AB)_{ij}^2.$$

*Proof.* Fix  $i, j$ . For  $t = 1, \dots, c$ , define  $X_t = \left(\frac{A^{(i_t)} B_{(i_t)}}{c p_{i_t}}\right)_{ij} = \frac{A_{i_t i_t} B_{i_t j}}{c p_{i_t}}$ . Thus,

$$\mathbf{E}[X_t] = \sum_{k=1}^n p_k \frac{A_{ik} B_{kj}}{c p_k} = \frac{1}{c} (AB)_{ij} \quad \text{and} \quad \mathbf{E}[X_t^2] = \sum_{k=1}^n \frac{A_{ik}^2 B_{kj}^2}{c^2 p_k}.$$

Since by construction  $(CR)_{ij} = \sum_{t=1}^c X_t$ , we have  $\mathbf{E}[(CR)_{ij}] = \sum_{t=1}^c \mathbf{E}[X_t] = (AB)_{ij}$ . Since  $(CR)_{ij}$  is the sum of  $c$  independent random variables,  $\mathbf{Var}[(CR)_{ij}] = \sum_{t=1}^c \mathbf{Var}[X_t]$ . Since  $\mathbf{Var}[X_t] = \mathbf{E}[X_t^2] - \mathbf{E}[X_t]^2$ , we see that

$$\mathbf{Var}[X_t] = \sum_{k=1}^n \frac{A_{ik}^2 B_{kj}^2}{c^2 p_k} - \frac{1}{c^2} (AB)_{ij}^2$$

and the lemma follows.  $\square$

Using this lemma, we bound  $\mathbf{E}[\|AB - CR\|_F^2]$  in the next lemma. In addition, we note how this measure of the error depends on the  $p_i$ 's.

LEMMA 4. *Suppose  $A \in \mathbb{R}^{m \times n}$ ,  $B \in \mathbb{R}^{n \times p}$ ,  $c \in \mathbb{Z}^+$  such that  $1 \leq c \leq n$ , and  $\{p_i\}_{i=1}^n$  are such that  $p_i \geq 0$  and  $\sum_{i=1}^n p_i = 1$ . Construct  $C$  and  $R$  with the BASICMATRIXMULTIPLICATION algorithm, and let  $CR$  be an approximation to  $AB$ .*

Then

$$(4) \quad \mathbf{E} \left[ \|AB - CR\|_F^2 \right] = \sum_{k=1}^n \frac{|A^{(k)}|^2 |B_{(k)}|^2}{cp_k} - \frac{1}{c} \|AB\|_F^2.$$

Furthermore, if

$$(5) \quad p_k = \frac{|A^{(k)}| |B_{(k)}|}{\sum_{k'=1}^n |A^{(k')}| |B_{(k')}|},$$

then

$$(6) \quad \mathbf{E} \left[ \|AB - CR\|_F^2 \right] = \frac{1}{c} \left( \sum_{k=1}^n |A^{(k)}| |B_{(k)}| \right)^2 - \frac{1}{c} \|AB\|_F^2.$$

This choice of  $p_k$  minimizes  $\mathbf{E}[\|AB - CR\|_F^2]$  among possible choices for the sampling probabilities.

*Proof.* First, note that

$$\mathbf{E} \left[ \|AB - CR\|_F^2 \right] = \sum_{i=1}^m \sum_{j=1}^p \mathbf{E} \left[ (AB - CR)_{ij}^2 \right] = \sum_{i=1}^m \sum_{j=1}^p \mathbf{Var} [(CR)_{ij}].$$

Thus, from Lemma 3 it follows that

$$\begin{aligned} \mathbf{E} \left[ \|AB - CR\|_F^2 \right] &= \frac{1}{c} \sum_{k=1}^n \frac{1}{p_k} \left( \sum_i A_{ik}^2 \right) \left( \sum_j B_{kj}^2 \right) - \frac{1}{c} \|AB\|_F^2 \\ &= \frac{1}{c} \sum_{k=1}^n \frac{1}{p_k} |A^{(k)}|^2 |B_{(k)}|^2 - \frac{1}{c} \|AB\|_F^2. \end{aligned}$$

If the value  $p_k = \frac{|A^{(k)}| |B_{(k)}|}{\sum_{k'=1}^n |A^{(k')}| |B_{(k')}|}$  is used in this expression, then

$$\mathbf{E} \left[ \|AB - CR\|_F^2 \right] = \frac{1}{c} \left( \sum_{k=1}^n |A^{(k)}| |B_{(k)}| \right)^2 - \frac{1}{c} \|AB\|_F^2.$$

Finally, to prove that this choice for the  $p_k$ 's minimizes  $\mathbf{E}[\|AB - CR\|_F^2]$  define the function

$$f(p_1, \dots, p_n) = \sum_{k=1}^n \frac{1}{p_k} |A^{(k)}|^2 |B_{(k)}|^2,$$

which characterizes the dependence of  $\mathbf{E}[\|AB - CR\|_F^2]$  on the  $p_k$ 's. To minimize  $f$  subject to  $\sum_{k=1}^n p_k = 1$ , introduce the Lagrange multiplier  $\lambda$  and define the function

$$g(p_1, \dots, p_n) = f(p_1, \dots, p_n) + \lambda \left( \sum_{k=1}^n p_k - 1 \right).$$

We then have at the minimum that

$$0 = \frac{\partial g}{\partial p_i} = \frac{-1}{p_i^2} |A^{(i)}|^2 |B_{(i)}|^2 + \lambda.$$

Thus,

$$p_i = \frac{|A^{(i)}| |B_{(i)}|}{\sqrt{\lambda}} = \frac{|A^{(i)}| |B_{(i)}|}{\sum_{i'=1}^n |A^{(i')}| |B_{(i')}|},$$

where the second equality comes from solving for  $\sqrt{\lambda}$  in  $\sum_{k=1}^{n-1} p_k = 1$ . That these probabilities are a minimum follows since  $\frac{\partial^2 g}{\partial p_i^2} > 0 \forall i$  such that  $|A^{(i)}|^2 |B_{(i)}|^2 > 0$ .  $\square$

**4.4. Analysis of the algorithm for nearly optimal probabilities.** With Lemma 4 and using Jensen's inequality, upper bounds on quantities such as  $\mathbf{E}[\|AB - CR\|_F^2]$  and  $\mathbf{E}[\|AB - CR\|_F]$  may be obtained for various sampling probabilities  $\{p_i\}_{i=1}^n$ . In many cases, by using a martingale argument to show that the error is tightly concentrated around its mean, the expectations in these bounds may be removed and the corresponding results can be shown to hold with high probability.

Rather than presenting these results in their full generality, we restrict our attention to two particular sets of probabilities. We will say that the sampling probabilities  $p_k = \frac{|A^{(k)}| |B_{(k)}|}{\sum_{k'=1}^n |A^{(k')}| |B_{(k')}|}$  are the *optimal probabilities* since they minimize  $\mathbf{E}[\|AB - CR\|_F^2]$ , which as Lemma 4 shows is one natural measure of the error. We will say that a set of sampling probabilities  $\{p_i\}_{i=1}^n$  are *nearly optimal probabilities* if  $p_k \geq \frac{\beta |A^{(k)}| |B_{(k)}|}{\sum_{k'=1}^n |A^{(k')}| |B_{(k')}|}$  for some positive constant  $\beta \leq 1$ .

We now prove, for nearly optimal sampling probabilities, results analogous to those of Lemma 4, and also that the corresponding results with the expectations removed hold with high probability. Notice that if  $\beta \neq 1$ , then we suffer a small  $\beta$ -dependent loss in accuracy.

**THEOREM 1.** *Suppose  $A \in \mathbb{R}^{m \times n}$ ,  $B \in \mathbb{R}^{n \times p}$ ,  $c \in \mathbb{Z}^+$  such that  $1 \leq c \leq n$ , and  $\{p_i\}_{i=1}^n$  are such that  $\sum_{i=1}^n p_i = 1$  and such that for some positive constant  $\beta \leq 1$*

$$(7) \quad p_k \geq \frac{\beta |A^{(k)}| |B_{(k)}|}{\sum_{k'=1}^n |A^{(k')}| |B_{(k')}|}.$$

*Construct  $C$  and  $R$  with the BASICMATRIXMULTIPLICATION algorithm, and let  $CR$  be an approximation to  $AB$ . Then*

$$(8) \quad \mathbf{E} \left[ \|AB - CR\|_F^2 \right] \leq \frac{1}{\beta c} \|A\|_F^2 \|B\|_F^2.$$

*Furthermore, let  $\delta \in (0, 1)$  and  $\eta = 1 + \sqrt{(8/\beta) \log(1/\delta)}$ . Then, with probability at least  $1 - \delta$ ,*

$$(9) \quad \|AB - CR\|_F^2 \leq \frac{\eta^2}{\beta c} \|A\|_F^2 \|B\|_F^2.$$

*Proof.* Following reasoning similar to that of Lemma 4 and using the probabilities

of (7), we see that

$$\begin{aligned} \mathbf{E} \left[ \|AB - CR\|_F^2 \right] &\leq \frac{1}{c} \sum_{k=1}^n \frac{1}{p_k} |A^{(k)}|^2 |B_{(k)}|^2 \\ &\leq \frac{1}{\beta c} \left( \sum_{k=1}^n |A^{(k)}| |B_{(k)}| \right)^2 \\ &\leq \frac{1}{\beta c} \|A\|_F^2 \|B\|_F^2, \end{aligned}$$

where the last inequality follows due to the Cauchy–Schwarz inequality. Next, define the event  $\mathcal{E}_2$  to be

$$(10) \quad \|AB - CR\|_F \leq \frac{\eta}{\sqrt{\beta c}} \|A\|_F \|B\|_F$$

and note that to prove the remainder of the theorem it suffices to prove that  $\mathbf{Pr}[\mathcal{E}_2] \geq 1 - \delta$ . To that end, note that  $C$  and  $R$  and thus  $CR = \sum_{t=1}^c \frac{1}{cp_{i_t}} A^{i_t} B_{i_t}$  are formed by randomly selecting  $c$  elements from  $\{1, \dots, n\}$ , independently and with replacement. Let the sequence of elements chosen be  $\{i_t\}_{t=1}^c$ . Consider the function

$$(11) \quad F(i_1, \dots, i_c) = \|AB - CR\|_F.$$

We will show that changing one  $i_t$  at a time does not change  $F$  too much; this will enable us to apply a martingale inequality. To this end, consider changing one of the  $i_t$  to  $i'_t$  while keeping the other  $i_t$ 's the same. Then construct the corresponding  $C'$  and  $R'$ . Note that  $C'$  differs from  $C$  in only a single column and that  $R'$  differs from  $R$  in only a single row. Thus,

$$(12) \quad \|CR - C'R'\|_F = \left\| \frac{A^{(i_t)} B_{(i_t)}}{cp_{i_t}} - \frac{A^{(i'_t)} B_{(i'_t)}}{cp_{i'_t}} \right\|_F$$

$$(13) \quad \leq \frac{1}{cp_{i_t}} \left\| A^{(i_t)} B_{(i_t)} \right\|_F + \frac{1}{cp_{i'_t}} \left\| A^{(i'_t)} B_{(i'_t)} \right\|_F$$

$$(14) \quad = \frac{1}{cp_{i_t}} |A^{(i_t)}| |B_{(i_t)}| + \frac{1}{cp_{i'_t}} |A^{(i'_t)}| |B_{(i'_t)}|$$

$$(15) \quad \leq \frac{2}{c} \max_{\alpha} \frac{|A^{(\alpha)}| |B_{(\alpha)}|}{p_{\alpha}}.$$

Equation (12) follows by construction and (14) follows since  $\|xy^T\|_F = |x| |y|$  for  $x \in \mathbb{R}^n$  and  $y \in \mathbb{R}^n$ . Thus, using the probabilities (7) and employing the Cauchy–Schwarz inequality we see that

$$(16) \quad \|CR - C'R'\|_F \leq \frac{2}{\beta c} \sum_{k=1}^n |A^{(k)}| |B_{(k)}|$$

$$(17) \quad \leq \frac{2}{\beta c} \|A\|_F \|B\|_F.$$

Therefore, using the triangle inequality we see that

$$(18) \quad \begin{aligned} \|AB - CR\|_F &\leq \|AB - C'R'\|_F + \|C'R' - CR\|_F \\ &\leq \|AB - C'R'\|_F + \frac{2}{\beta c} \|A\|_F \|B\|_F. \end{aligned}$$

By similar reasoning, we can derive

$$(19) \quad \|AB - C'R'\|_F \leq \|AB - CR\|_F + \frac{2}{\beta c} \|A\|_F \|B\|_F.$$

Define  $\Delta = \frac{2}{\beta c} \|A\|_F \|B\|_F$ ; thus,

$$(20) \quad |F(i_1, \dots, i_k, \dots, i_c) - F(i_1, \dots, i'_k, \dots, i_c)| \leq \Delta.$$

Let  $\gamma = \sqrt{2c \log(1/\delta)} \Delta$  and consider the associated Doob martingale. By the Hoeffding–Azuma inequality [22],

$$(21) \quad \Pr \left[ \|AB - CR\|_F \geq \frac{1}{\sqrt{\beta c}} \|A\|_F \|B\|_F + \gamma \right] \leq \exp(-\gamma^2/2c\Delta^2) = \delta$$

and the theorem follows.  $\square$

An immediate consequence of Theorem 1 is that by choosing enough column-row pairs, the error in the approximation of the matrix product can be made arbitrarily small. In particular, if  $c \geq 1/\beta\epsilon^2$ , then by using Jensen’s inequality it follows that

$$(22) \quad \mathbf{E} [\|AB - CR\|_F] \leq \epsilon \|A\|_F \|B\|_F$$

and if, in addition,  $c \geq \eta^2/\beta\epsilon^2$ , then with probability at least  $1 - \delta$

$$(23) \quad \|AB - CR\|_F \leq \epsilon \|A\|_F \|B\|_F.$$

In certain applications, e.g., [11, 12], one is interested in an application of Theorem 1 to the case that  $B = A^T$ , i.e., one is interested in approximating  $\|AA^T - CC^T\|_F^2$ . In this case, sampling column-row pairs corresponds to sampling columns of  $A$ , and nearly optimal probabilities will be those such that  $p_k \geq \frac{\beta |A^{(k)}|^2}{\|A\|_F^2}$  for some positive  $\beta \leq 1$ . By taking  $B = A^T$  and applying Jensen’s inequality, we have the following theorem as a corollary of Theorem 1.

**THEOREM 2.** *Suppose  $A \in \mathbb{R}^{m \times n}$ ,  $c \in \mathbb{Z}^+$ ,  $1 \leq c \leq n$ , and  $\{p_i\}_{i=1}^n$  are such that  $\sum_{i=1}^n p_i = 1$  and such that  $p_k \geq \frac{\beta |A^{(k)}|^2}{\|A\|_F^2}$  for some positive constant  $\beta \leq 1$ . Furthermore, let  $\delta \in (0, 1)$  and  $\eta = 1 + \sqrt{(8/\beta) \log(1/\delta)}$ . Construct  $C$  (and  $R = C^T$ ) with the BASICMATRIXMULTIPLICATION algorithm, and let  $CC^T$  be an approximation to  $AA^T$ . Then*

$$(24) \quad \mathbf{E} [\|AA^T - CC^T\|_F] \leq \frac{1}{\sqrt{\beta c}} \|A\|_F^2$$

and with probability at least  $1 - \delta$ ,

$$(25) \quad \|AA^T - CC^T\|_F \leq \frac{\eta}{\sqrt{\beta c}} \|A\|_F^2.$$

**5. A second matrix multiplication algorithm.** In this section we describe the ELEMENTWISEMATRIXMULTIPLICATION algorithm to approximate the product of two matrices. First, in section 5.1, we describe the algorithm, its implementation, and running time issues; then in section 5.2 we analyze the algorithm and bound its error with respect to both the Frobenius and spectral norms. We will see that the algorithm returns good approximations with respect to the spectral norm but not with respect to the Frobenius norm.

ELEMENTWISEMATRIXMULTIPLICATION Algorithm.

**Input:**  $A \in \mathbb{R}^{m \times n}$ ,  $B \in \mathbb{R}^{n \times p}$ ,  $\{p_{ij}\}_{i,j=1}^{m,n}$  such that  $0 \leq p_{ij} \leq 1$ , and  $\{q_{ij}\}_{i,j=1}^{n,p}$  such that  $0 \leq q_{ij} \leq 1$ .

**Output:**  $S \in \mathbb{R}^{m \times n}$  and  $R \in \mathbb{R}^{n \times p}$ .

**Algorithm:**

1. For  $i = 1$  to  $m$  and  $j = 1$  to  $n$ , independently,
  - (a) Set

$$S_{ij} = \begin{cases} A_{ij}/p_{ij} & \text{with probability } p_{ij}, \\ 0 & \text{otherwise.} \end{cases}$$

2. For  $i = 1$  to  $n$  and  $j = 1$  to  $p$ , independently,
  - (a) Set

$$R_{ij} = \begin{cases} B_{ij}/q_{ij} & \text{with probability } q_{ij}, \\ 0 & \text{otherwise.} \end{cases}$$

3. Return  $S, R$ .

FIG. 4. *The ELEMENTWISEMATRIXMULTIPLICATION algorithm.*

**5.1. The algorithm and its implementation.** The method to approximate the product of two matrices that is presented in this section differs from the previous algorithm and is inspired by [2] and [1]. In [2] the singular value decomposition of a matrix is approximated using elementwise uniform sampling; in [1] this approach is extended to include nonuniform sampling probabilities of a certain natural form. Since neither of these papers applies these methods to approximate matrix multiplication, we do so here for comparison with the BASICMATRIXMULTIPLICATION algorithm.

Consider the ELEMENTWISEMATRIXMULTIPLICATION algorithm presented in Figure 4. When this algorithm is given as input two matrices  $A \in \mathbb{R}^{m \times n}$  and  $B \in \mathbb{R}^{n \times p}$  it creates two matrices  $S \in \mathbb{R}^{m \times n}$  and  $R \in \mathbb{R}^{n \times p}$  by keeping a few elements of  $A$  and a few elements of  $B$ , respectively, scaling in an appropriate manner those elements that are kept, and zeroing out the remaining elements. The algorithm then returns matrices  $S$  and  $R$  such that the product  $SR$  is an approximation to  $AB$ . Note that since  $S$  and  $R$  are formed independently of each other the algorithm does not keep “corresponding” elements; doing so would introduce dependence that would complicate the analysis.

The ELEMENTWISEMATRIXMULTIPLICATION algorithm can be implemented with the nonuniform probabilities used in this section with two passes over the data; we leave it as an open problem whether a single pass suffices when working within the pass-efficient framework. This algorithm differs from the BASICMATRIXMULTIPLICATION algorithm in that we get an expected number of elements so we have an expected additional space required for storage and an expected additional time required for the associated sparse matrix multiplication. We do not provide a detailed analysis of these random variables.

**5.2. Analysis of the algorithm.** In this section we present error bounds for both  $\|AB - SR\|_F$  and  $\|AB - SR\|_2$ . While the Frobenius norm error bound for this algorithm is rather easy to derive using very intuitive probability distributions, the spectral norm bound is more complicated and requires some additional technicalities.

Since whether or not (for a given  $i, j$ )  $S_{ij} = 0$  or  $S_{ij} = A_{ij}/p_{ij}$  we have that  $A_{ij} - S_{ij}$  is large (and similarly for the matrix  $R$  and thus the matrix  $SR$ ) it is plausible that the ELEMENTWISEMATRIXMULTIPLICATION algorithm does not have a good bound for  $\mathbf{E}[\|AB - SR\|_F^2]$ . This intuition is formalized in the following lemma. Note that  $\ell$  and  $\ell'$  are chosen such that not more than  $\ell$  and  $\ell'$  of the elements of the matrices  $A$  and  $B$  are retained in expectation, respectively.

LEMMA 5. *Suppose  $A \in \mathbb{R}^{m \times n}$  and  $B \in \mathbb{R}^{n \times p}$ , let  $\ell, \ell' \in \mathbb{Z}^+$ , and let  $p_{ij} = \min\{1, \ell A_{ij}^2 / \|A\|_F^2\}$  and  $q_{ij} = \min\{1, \ell' B_{ij}^2 / \|B\|_F^2\}$ . Construct  $S$  and  $R$  with the ELEMENTWISEMATRIXMULTIPLICATION algorithm, and let  $SR$  be an approximation to  $AB$ . Then,  $\forall i, j$ ,*

$$\mathbf{E}[(SR)_{ij}] = (AB)_{ij},$$

$$\mathbf{Var}[(SR)_{ij}] = \sum_{k=1}^n \frac{A_{ik}^2}{p_{ik}} \frac{B_{kj}^2}{q_{kj}} - \sum_{k=1}^n A_{ik}^2 B_{kj}^2$$

$$(26) \quad \mathbf{E}[\|AB - SR\|_F^2] \geq \frac{mpn}{\ell\ell'} \|A\|_F^2 \|B\|_F^2 - \sum_{k=1}^n |A^{(k)}|^2 |B_{(k)}|^2.$$

*Proof.* Let us first fix  $i, j$ . Then, since for every  $k$  we have that  $S_{ik} = A_{ik}/p_{ik}$  with probability  $p_{ik}$  and  $S_{ik} = 0$  with probability  $1 - p_{ik}$ , we have that  $\mathbf{E}[S_{ik}] = A_{ik}$ ; similarly for  $R_{kj}$ , we have that  $\mathbf{E}[R_{kj}] = B_{kj}$ . Thus, since  $S$  and  $R$  have been constructed independently, we have that

$$\mathbf{E}[(SR)_{ij}] = \mathbf{E}\left[\sum_{k=1}^n S_{ik} R_{kj}\right] = \sum_{k=1}^n \mathbf{E}[S_{ik}] \mathbf{E}[R_{kj}] = (AB)_{ij}.$$

Since  $\mathbf{Var}[(SR)_{ij}] = \mathbf{E}[(SR)_{ij}^2] - \mathbf{E}[(SR)_{ij}]^2$  and since  $(SR)_{ij} = \sum_{k=1}^n S_{ik} R_{kj}$  we get that

$$\begin{aligned} \mathbf{Var}[(SR)_{ij}] &= \sum_{k_1=1}^n \sum_{k_2=1}^n \mathbf{E}[S_{ik_1} R_{k_1j} S_{ik_2} R_{k_2j}] - \mathbf{E}[(SR)_{ij}]^2 \\ &= \sum_{k=1}^n \mathbf{E}[S_{ik}^2] \mathbf{E}[R_{kj}^2] + \sum_{k_1=1}^n \sum_{k_2 \neq k_1}^n \mathbf{E}[S_{ik_1}] \mathbf{E}[R_{k_1j}] \mathbf{E}[S_{ik_2}] \mathbf{E}[R_{k_2j}] - (AB)_{ij}^2 \\ &= \sum_{k=1}^n \frac{A_{ik}^2}{p_{ik}} \frac{B_{kj}^2}{q_{kj}} + \sum_{k_1=1}^n \sum_{k_2 \neq k_1}^n A_{ik_1} B_{k_1j} A_{ik_2} B_{k_2j} - (AB)_{ij}^2 \\ &= \sum_{k=1}^n \frac{A_{ik}^2}{p_{ik}} \frac{B_{kj}^2}{q_{kj}} - \sum_{k=1}^n A_{ik}^2 B_{kj}^2, \end{aligned}$$

where the last line follows by adding and subtracting  $\sum_{k_1=1}^n \sum_{k_2=k_1}^n A_{ik_1} B_{k_1j} A_{ik_2} B_{k_2j}$  from the second-to-last line.

Thus, since  $\mathbf{E}[\|AB - SR\|_F^2] = \sum_{i=1}^m \sum_{j=1}^p \mathbf{Var}[(SR)_{ij}]$  and since the probabilities  $p_{ij}$  and  $q_{ij}$  are such that  $1/p_{ik} \geq \|A\|_F^2 / \ell A_{ik}^2$  and  $1/q_{kj} \geq \|B\|_F^2 / \ell' B_{kj}^2$  we get

that

$$\begin{aligned} \mathbf{E} \left[ \|AB - SR\|_F^2 \right] &= \sum_{i=1}^m \sum_{j=1}^p \sum_{k=1}^n \frac{A_{ik}^2 B_{kj}^2}{p_{ik} q_{kj}} - \sum_{i=1}^m \sum_{j=1}^p \sum_{k=1}^n A_{ik}^2 B_{kj}^2 \\ &\geq \sum_{i,j=1}^{m,p} \sum_{k=1}^n \frac{\|A\|_F^2 \|B\|_F^2}{\ell \ell'} - \sum_{k=1}^n |A^{(k)}|^2 |B_{(k)}|^2. \end{aligned}$$

The lemma then follows.  $\square$

Next we show that although the ELEMENTWISEMATRIXMULTIPLICATION algorithm does not yield a nice error bound for the Frobenius norm, it does for the spectral norm. In order to prove Theorem 4, which provides our bound on  $\|AB - SR\|_2$ , we will use the following theorem, which follows immediately from a result that was proved in [1] and which shows that with high probability the spectrum of a random matrix is close to its expectation. The theorem is proved by using a generalization of a result of Füredi and Komlós [16], combined with a more recent concentration result of Krivelevich and Vu based on Talagrand's inequality [21].

**THEOREM 3.** *Given an  $n \times n$  matrix  $A$ , let  $\hat{A}$  be any random matrix whose entries are independent random variables such that  $\forall i, j$ ,  $\mathbf{E}[\hat{A}_{ij}] = A_{ij}$ ,  $\mathbf{Var}[\hat{A}_{ij}] \leq \sigma^2$ , and*

$$(27) \quad \left| \hat{A}_{ij} - A_{ij} \right| \leq \frac{\sigma \sqrt{2n}}{\log^3(2n)}.$$

For any  $n \geq 10$ , with probability at least  $1 - 1/(2n)$ ,

$$(28) \quad \|A - \hat{A}\|_2 < 7\sigma \sqrt{2n}.$$

Prior to stating the main result of this section, we must address a technical issue that arises in our effort to apply the above theorem in order to bound  $\|AB - SR\|_2$ . Note that the construction of the matrices  $S$  and  $R$  by the ELEMENTWISEMATRIXMULTIPLICATION algorithm may be viewed as adding carefully constructed random matrices  $E$  and  $D$  such that  $S = A + E$  and  $R = B + D$ ; see [2] and [1] for a discussion. As we will see below, if we can bound  $\|E\|_2$  and  $\|D\|_2$ , then a bound for  $\|AB - SR\|_2$  follows easily. Since we will apply Theorem 3 in order to obtain such bounds, we need to satisfy the range constraint (27). Sampling with respect to the nonuniform probability distribution of Lemma 5 might violate this constraint since, in the unlikely event that a small element is kept, the resulting entry  $S_{ij} = A_{ij}/p_{ij}$  will be very large (and similarly for  $R$ ). Thus, following [1], we modify our sampling probabilities so that small elements are kept with a slightly larger probability which is proportional to  $|A_{ij}|$  instead of  $A_{ij}^2$ :

$$(29) \quad p_{ij} = \begin{cases} \min\{1, \ell A_{ij}^2 / \|A\|_F^2\} & \text{if } |A_{ij}| > \frac{\|A\|_F \log^3(2n)}{\sqrt{2n\ell}}, \\ \min\left\{1, \frac{\sqrt{\ell}|A_{ij}| \log^3(2n)}{\sqrt{2n}\|A\|_F}\right\} & \text{otherwise,} \end{cases}$$

$$(30) \quad q_{ij} = \begin{cases} \min\{1, \ell' B_{ij}^2 / \|B\|_F^2\} & \text{if } |B_{ij}| > \frac{\|B\|_F \log^3(2n)}{\sqrt{2n\ell'}}, \\ \min\left\{1, \frac{\sqrt{\ell'}|B_{ij}| \log^3(2n)}{\sqrt{2n}\|B\|_F}\right\} & \text{otherwise.} \end{cases}$$

We now state and prove our main theorem of this section. In the interests of clarity we make several simplifying assumptions in the statement of the theorem.

**THEOREM 4.** *Suppose  $A \in \mathbb{R}^{m \times n}$ ,  $B \in \mathbb{R}^{n \times p}$ , and let  $p_{ij}$  and  $q_{ij}$  be as specified in (29) and (30) with  $\ell = \ell' \geq 1$ . Assume that  $\ell \leq \|A\|_F^2 / \max_{i,j} A_{ij}^2$  and that  $\ell \leq \|B\|_F^2 / \max_{i,j} B_{ij}^2$ ; assume also that  $m = n = p$  and that  $n$  is large enough so that  $2n \geq \log^6(2n)$ . Construct  $S$  and  $R$  with the ELEMENTWISEMATRIXMULTIPLICATION algorithm, and let  $SR$  be an approximation to  $AB$ . Then, with probability at least  $1 - 1/n$ ,*

$$(31) \quad \|AB - SR\|_2 \leq \left(20\sqrt{\frac{n}{\ell}} + \frac{100n}{\ell}\right) \|A\|_F \|B\|_F.$$

*Proof.* By the assumptions on  $n$  and  $\ell$ , neither  $p_{ij}$  nor  $q_{ij}$  exceed 1 for any  $i, j$ . Letting  $E = S - A$  and  $D = R - B$ , we have

$$(32) \quad SR = (A + E)(B + D) = AB + AD + EB + ED.$$

Thus, by the triangle inequality and submultiplicativity, we have that

$$(33) \quad \|AB - SR\|_2 \leq \|A\|_2 \|D\|_2 + \|E\|_2 \|B\|_2 + \|E\|_2 \|D\|_2.$$

In order to apply Theorem 3 to  $\|E\|_2$  and  $\|D\|_2$  we first verify that the assumptions of the theorem are satisfied. From the proof of Lemma 5, we have that  $\mathbf{E}[S_{ij}] = A_{ij}$ . In addition,

$$\mathbf{Var}[S_{ij}] \leq \mathbf{E}[S_{ij}^2] = \frac{A_{ij}^2}{p_{ij}} \leq \frac{\|A\|_F^2}{\ell}$$

holds regardless of whether  $|A_{ij}|$  is larger or smaller than the threshold. Similarly, we get that  $\mathbf{E}[R_{ij}] = B_{ij}$  and that  $\mathbf{Var}[D_{ij}] \leq \frac{\|B\|_F^2}{\ell}$ . It is straightforward to show that regardless of whether or not  $|A_{ij}|$  is above or below the threshold and regardless of whether or not  $S_{ij} = 0$  or  $S_{ij} = A_{ij}/p_{ij}$  we have that

$$(34) \quad |A_{ij} - S_{ij}| \leq \frac{\|A\|_F \sqrt{2n}}{\sqrt{\ell} \log^3(2n)}.$$

Similarly, one can show that

$$(35) \quad |B_{ij} - R_{ij}| \leq \frac{\|B\|_F \sqrt{2n}}{\sqrt{\ell} \log^3(2n)}.$$

Thus, the conditions of Theorem 3 are satisfied and with probability at least  $1 - 1/2n$  each of the following holds:

$$(36) \quad \|E\|_2 \leq 7 \|A\|_F \sqrt{2n}/\sqrt{\ell},$$

$$(37) \quad \|D\|_2 \leq 7 \|B\|_F \sqrt{2n}/\sqrt{\ell}.$$

Thus, with probability at least  $1 - 1/n$  both of these inequalities hold. Combining the bounds (36) and (37) with (33), and since  $\|\cdot\|_2 \leq \|\cdot\|_F$ , we have

$$\begin{aligned} \|AB - SR\|_2 &\leq \|A\|_2 \|D\|_2 + \|E\|_2 \|B\|_2 + \|E\|_2 \|D\|_2 \\ &\leq \frac{7\sqrt{2n} \|A\|_F \|B\|_F}{\sqrt{\ell}} + \frac{7\sqrt{2n} \|A\|_F \|B\|_F}{\sqrt{\ell}} + \frac{98n \|A\|_F \|B\|_F}{\ell} \\ &\leq (20\sqrt{n/\ell} + 100n/\ell) \|A\|_F \|B\|_F. \quad \square \end{aligned}$$

Notice that if we let  $\ell = cn$  in Theorem 4, then the error bound (31) becomes

$$\|AB - SR\|_2 \leq \left( \frac{20}{\sqrt{c}} + \frac{100}{c} \right) \|A\|_F \|B\|_F = O(1/\sqrt{c}) \|A\|_F \|B\|_F.$$

Comparison with (9) of Theorem 1 reveals that (since  $\|\cdot\|_2 \leq \|\cdot\|_F$ ) both of our matrix multiplication algorithms have, asymptotically, a similar bound with respect to the spectral norm.

**6. Discussion and conclusion.** To the best of our knowledge, the only previous randomized algorithm that approximates the product of two matrices is that of Cohen and Lewis [7]. This algorithm is based on random walks in a graph representation of the input matrices and attempts to identify all high-valued entries in nonnegative matrix products in order to improve estimates (relative to exact sparse multiplication) by spending less time on small-valued entries. Their algorithm is more complicated than ours, it requires different graph representations of the input matrices if the matrices are allowed to contain negative entries, it needs to store the complete input matrices, and it is especially useful when the matrices are not sparse.

It is worth emphasizing how the BASICMATRIXMULTIPLICATION algorithm behaves when  $A$  and  $B$  are well approximated by low-rank matrices. Since a low-rank matrix or a matrix that is well approximated by a low-rank matrix is a matrix whose rows and columns contain much redundant information in terms of the subspaces they span, it is plausible that if the range of  $B$  overlaps appropriately with the domain of  $A$ , then we can get a good approximation to  $AB$  by carefully sampling a small number  $c$  of appropriately rescaled rank-one approximations to  $AB$ . Theorem 1 shows that if the  $\{p_i\}_{i=1}^n$  are chosen judiciously, then this is the case and Figure 3 illustrates this.

We emphasize that in the case of sampling with nonuniform probabilities our sampling can be viewed as a two-pass algorithm; in the first pass the algorithm reads the matrix, it then decides which columns and rows to keep, and then in the second pass it extracts these columns and rows. In certain applications, two passes through the matrix are not possible and only one pass is allowed [14]. In these cases, we can still perform uniform sampling; in this case, if column-row pairs are all approximately the same size, i.e.,  $|A^{(k)}||B_{(k)}|$  is close to its mean value (more precisely, if there exists some positive constant  $\beta \leq 1$  such that  $\forall k |A^{(k)}||B_{(k)}| \leq \frac{1}{\beta n} \sum_{k'=1}^n |A^{(k')}||B_{(k')}|$ ), then the uniform probabilities are nearly optimal and we can sample uniformly with a small  $\beta$ -dependent loss in accuracy.

Note that although larger columns and rows get picked more often, the scaling is such that their weight is deemphasized in the estimator sum. One could imagine a situation when detailed information about the elements of, e.g.,  $A$  may be obtained after a single pass but no information or no information except general bounds on the size of the elements may be possible for  $B$ . In this case, a set of sampling probabilities other than those discussed in section 4 may be appropriate. See Table 1 for a summary of the results for different probability distributions; these results are proven in section A.3

The ELEMENTWISEMATRIXMULTIPLICATION algorithm has been presented for completeness and because in some applications its use may be more appropriate than the use of the BASICMATRIXMULTIPLICATION algorithm. It is worth emphasizing that the ELEMENTWISEMATRIXMULTIPLICATION algorithm achieves its spectral norm bound since its sampling procedure may be viewed as adding a carefully constructed random perturbation to every element of the original matrix; see [2, 1] for a nice discussion of these ideas.

Recent work has focused on establishing lower bounds on the number of queries a sampling algorithm is required to perform in order to approximate a given function accurately with low probability of error; see, e.g., [4]. See also [24, 27] for recent related work.

**Appendix. Further analysis of the basic matrix multiplication algorithm.** In this section we provide further analysis of the BASICMATRIXMULTIPLICATION algorithm. In section A.1 we consider approximating the product of more than two matrices by a similar sampling process. Then, in section A.2 we examine element-wise error bounds for the algorithm, and in section A.3 we consider error bounds for probability distributions which are not nearly optimal in the sense of section 4.4.

**A.1. Approximating the product of more than two matrices.** In this section we consider the task of approximating the product of three or more matrices using the ideas of the BASICMATRIXMULTIPLICATION algorithm of section 4. For simplicity our exposition will be restricted to the case of approximating the product  $ABC$  of three matrices. Recall that given matrices  $A \in \mathbb{R}^{m \times n}$ ,  $B \in \mathbb{R}^{n \times p}$ ,  $C \in \mathbb{R}^{p \times q}$ , the product  $ABC$  may be written as

$$(38) \quad ABC = \sum_{s=1}^n \sum_{t=1}^p A^{(s)} B_{st} C_{(t)}.$$

One possible way of extending the ideas of section 4.1 is the following. Randomly choose  $i_s \in \{1, \dots, n\}$  independently and with replacement  $c_1$  times according to a probability distribution  $\{p_i\}_{i=1}^n$  and randomly choose  $j_t \in \{1, \dots, p\}$  independently

FIG. 5. Diagram for the algorithm to approximately multiply three matrices.

and with replacement  $c_2$  times according to a probability distribution  $\{q_j\}_{j=1}^p$ . Then form the matrix  $\tilde{A} \in \mathbb{R}^{m \times c_1}$  with columns  $\tilde{A}^{(s)} = A^{(i_s)} / \sqrt{c_1 p_{i_s}}$ , the matrix  $\tilde{B} \in \mathbb{R}^{c_1 \times c_2}$  with elements  $\tilde{B}_{st} = B_{i_s j_t} / \sqrt{c_1 c_2 p_{i_s} q_{j_t}}$ , and the matrix  $\tilde{C} \in \mathbb{R}^{c_2 \times q}$  with rows  $\tilde{C}_{(t)} = C_{(j_t)} / \sqrt{c_2 q_{j_t}}$  so that

$$\tilde{A}\tilde{B}\tilde{C} = \sum_{s=1}^{c_1} \sum_{t=1}^{c_2} \frac{A^{(i_s)} B_{i_s j_t} C_{(j_t)}}{c_1 c_2 p_{i_s} q_{j_t}}.$$

Figure 5 presents a diagram illustrating the action of the algorithm just described to approximate the product of three matrices. One could then define sampling matrices  $S^{(A,c_1)}$  and  $S^{(C,c_2)}$  and diagonal rescaling matrices  $D^{\{p_k\}}$  and  $D^{\{q_k\}}$  in a manner analogous to that of section 4.1 and as indicated in Figure 5. Then  $\tilde{A}\tilde{B}\tilde{C} = AS^{(A,c_1)}D^{\{p_k\}^2}S^{(A,c_1)T}BS^{(C,c_2)}D^{\{q_k\}^2}S^{(C,c_2)T}C \approx ABC$ . An intuitively appealing aspect of this algorithm is that the product  $ABC$  is shown as  $C$ ,  $B$ , and then  $A$  operating between the high-dimensional  $\mathbb{R}^q$  and  $\mathbb{R}^m$  via the high-dimensional  $\mathbb{R}^p$  and  $\mathbb{R}^n$ ; this is approximated by  $\tilde{A}\tilde{B}\tilde{C}$ , which acts between  $\mathbb{R}^q$  and  $\mathbb{R}^m$  via the low-dimensional subspaces  $\mathbb{R}^{c_2}$  and  $\mathbb{R}^{c_1}$ . One difficulty with this algorithm is that its analysis is quite complicated due to the correlation in the nonindependent sampling of the elements of the matrix  $B$ .

A second way of extending the ideas of section 4.1 is the following. Randomly choose  $(i_s, j_t) \in \{1, \dots, n\} \times \{1, \dots, p\}$  independently and with replacement  $c$  times according to a probability distribution  $\{p_{kl}\}_{(k,l)=1}^{n,p}$ . This corresponds to sampling  $c$  terms from the sum (38). Then define

$$P = \sum_{u \equiv (s,t)=1}^c \frac{1}{c p_{k_s l_t}} A^{(k_s)} B_{k_s l_t} C_{(l_t)},$$

where the summation is a single sum over the  $c$  pairs  $(k_s, l_t) \in \{1, \dots, n\} \times \{1, \dots, p\}$  chosen by the algorithm. In this second algorithm the subspace interpretation of the first algorithm is lost but the analysis simplifies considerably. Using ideas similar to those in section 4 we can prove the following lemma about this algorithm.

LEMMA 6. *Given matrices  $A \in \mathbb{R}^{m \times n}$ ,  $B \in \mathbb{R}^{n \times p}$ ,  $C \in \mathbb{R}^{p \times q}$ , construct an approximation  $P$  to the product  $ABC$  by sampling as described in the second algorithm above with probabilities  $\{p_{k,l}\}_{(k,l)=1}^{n,p}$ . Then, for every  $i, j$  we have that  $\mathbf{E}[(P)_{ij}] = (ABC)_{ij}$  and that*

$$\mathbf{Var}[(P)_{ij}] = \frac{1}{c} \sum_{k=1}^n \sum_{l=1}^p \frac{1}{p_{kl}} A_{ik}^2 B_{kl}^2 C_{lj}^2 - \frac{1}{c} (ABC)_{ij}^2.$$

In addition,

$$\mathbf{E} \left[ \|ABC - P\|_F^2 \right] = \frac{1}{c} \sum_{k=1}^n \sum_{l=1}^p \frac{1}{p_{kl}} |A^{(k)}|^2 B_{kl}^2 |C_{(l)}|^2 - \frac{1}{c} \|ABC\|_F^2$$

and the probabilities

$$p_{kl} = \frac{|A^{(k)}| |B_{kl}| |C_{(l)}|}{\sum_{k'} \sum_{l'} |A^{(k')}| |B_{k'l'}| |C_{(l')}|}$$

minimize  $\mathbf{E}[\|ABC - P\|_F^2]$

*Proof.* The proof is similar to those of Lemmas 3 and 4.  $\square$

As in section 4.4 we will define probabilities  $\{p_{kl}\}$  to be nearly optimal if

$$p_{kl} \geq \beta \frac{|A^{(k)}| |B_{kl}| |C_{(l)}|}{\sum_{k'} \sum_{l'} |A^{(k')}| |B_{k'l'}| |C_{(l')}|}$$

for some  $\beta \leq 1$ . If sampling is performed with these probabilities, one can show that

$$\mathbf{E} \left[ \|ABC - P\|_F^2 \right] \leq \frac{1}{c\beta} \sum_k \sum_l |A^{(k)}| |B_{kl}| |C_{(l)}|,$$

and a similar result can be shown to hold with high probability.

Unfortunately, computing the optimal probabilities in the general case is not pass-efficient since it would require  $O(np)$  additional space and time. This situation would be relatively worse if one wanted to compute the product of more than three matrices, rendering this method uncompetitive with the exact algorithm. On the other hand, if the matrices are known to have a special structure or if the data are presented in a more specialized format, then this algorithm may be useful. For example, if it is known that none of the elements of  $B$  are too big, i.e., that the elements of  $B$  are such that there exists a  $\xi_B$  such that  $\forall i, j$  we have that  $B_{ij} \leq \xi_B \|B\|_F^2 / np$ , then there will exist a set of probabilities that are nearly optimal that do not depend on  $B$  and that can be computed efficiently.

**A.2. Elementwise error bounds.** In this section we provide elementwise error bounds on  $|(AB)_{ij} - (CR)_{ij}|$  for the BASICMATRIXMULTIPLICATION algorithm for two different probability distributions. We have the following lemma.

LEMMA 7. *Suppose  $A \in \mathbb{R}^{m \times n}$ ,  $B \in \mathbb{R}^{n \times p}$ ,  $c \in \mathbb{Z}^+$  such that  $1 \leq c \leq n$ , and  $\{p_i\}_{i=1}^n$  are such that  $p_i \geq 0$  and  $\sum_{i=1}^n p_i = 1$ . Let  $M$  be such that  $|A_{ij}| \leq M$  and  $|B_{ij}| \leq M$  for every appropriate  $i, j$ . Construct  $C$  and  $R$  with the BASICMATRIXMULTIPLICATION algorithm, and let  $CR$  be an approximation to  $AB$ . If  $p_k = 1/n$  for every  $k$ , then for every  $\delta > 0$  with probability at least  $1 - \delta$*

$$(39) \quad |(AB)_{ij} - (CR)_{ij}| < \frac{nM^2}{\sqrt{c}} \sqrt{8 \ln(2mp/\delta)} \quad \forall i, j.$$

If  $p_k \geq \frac{\beta |A^{(k)}| |B_{(k)}|}{\sum_{k'=1}^n |A^{(k')}| |B_{(k')}|}$  for some positive constant  $\beta \leq 1$ , then for every  $\delta > 0$  with probability at least  $1 - \delta$

$$(40) \quad |(AB)_{ij} - (CR)_{ij}| < \frac{n\sqrt{mp}M^2}{\sqrt{\beta c}} \sqrt{(8/\beta) \ln(2mp/\delta)} \quad \forall i, j.$$

*Proof.* Let us first consider the case of uniform sampling probabilities, i.e., when  $p_k = 1/n$ . First, fix attention on one particular  $(i, j) \in (\{1, \dots, m\}, \{1, \dots, p\})$ . Define  $X_t^{(ij)} = \left(\frac{A^{(it)}B_{(it)}}{cp_{i_t}}\right)_{ij} = \frac{A_{i_t i_t} B_{i_t j}}{cp_{i_t}}$ . From Lemma 3 we see that  $\mathbf{E}[X_t^{(ij)}] = \frac{1}{c}(AB)_{ij}$ . Define  $Y_t^{(ij)} = X_t^{(ij)} - \frac{1}{c}(AB)_{ij}$ ,  $t = 1, \dots, c$ , and note that the  $Y_t$ 's are independent random variables with  $\mathbf{E}[Y_t^{(ij)}] = 0$  for every  $t = 1, \dots, c$ . In addition,

$$(41) \quad \begin{aligned} |Y_t^{(ij)}| &\leq \left| \frac{A_{i_t i_t} B_{i_t j}}{cp_{i_t}} \right| + \left| \frac{1}{c}(AB)_{ij} \right| \\ &\leq \left| \frac{A_{i_t i_t} B_{i_t j}}{cp_{i_t}} \right| + \frac{nM^2}{c} \end{aligned}$$

$$(42) \quad \leq \frac{2nM^2}{c}.$$

Inequality (42) follows since for the uniform probabilities  $\left|\frac{A_{i_t i_t} B_{i_t j}}{cp_{i_t}}\right| \leq \frac{nM^2}{c}$ . By combining the upper and lower bounds provided by (42) with Hoeffding's inequality, we have that for any  $t > 0$

$$(43) \quad \Pr \left[ \left| \sum_{t=1}^c Y_t^{(ij)} \right| \geq ct \right] \leq 2 \exp \left( - \frac{2c^2 t^2}{\sum_{i=1}^c (4nM^2/c)^2} \right) = 2 \exp \left( - \frac{c^3 t^2}{8n^2 M^4} \right).$$

Define the event  $\mathcal{E}_{ij}$  to be  $|\sum_{t=1}^c Y_t^{(ij)}| \geq ct$  and the event  $\mathcal{E} = \bigcup_{i=1}^m \bigcup_{j=1}^p \mathcal{E}_{ij}$ . If we then let  $t = nM^2 \frac{2\sqrt{2}}{c^3} \sqrt{\ln(2mp/\delta)}$ , then by (43) we have that  $\Pr[\mathcal{E}_{ij}] \leq \frac{\delta}{mp}$ . Thus, (39) then follows since

$$\Pr[\mathcal{E}] \leq \sum_{i=1}^m \sum_{j=1}^p \Pr[\mathcal{E}_{ij}] \leq \sum_{ij} \delta/mp = \delta.$$

When applied to the nonuniform probabilities  $p_k \geq \frac{\beta |A^{(k)}| |B_{(k)}|}{\sum_{k'=1}^n |A^{(k')}| |B_{(k')}|}$  a similar line of reasoning establishes (40). The key step is to note that when using these probabilities we have that

$$(44) \quad \left| \frac{A_{i_t i_t} B_{i_t j}}{cp_{i_t}} \right| \leq \left| \frac{A_{i_t i_t} B_{i_t j}}{c\beta |A^{(k)}| |B_{(k)}|} \sum_{k'=1}^n |A^{(k')}| |B_{(k')}| \right| \leq \left| \frac{n\sqrt{mp}}{c\beta} M^2 \right|.$$

Since  $nM^2/c \leq n\sqrt{mp}M^2/(c\beta)$  this, when combined with (41), implies that

$$(45) \quad |Y_t^{(ij)}| \leq \frac{2n\sqrt{mp}M^2}{c\beta},$$

which provides the upper and lower bounds on the random variable required to apply Hoeffding's inequality.  $\square$

When the uniform probabilities are used

$$\|AB - CR\|_F^2 = \sum_{ij} |(AB)_{ij} - (CR)_{ij}|^2 \leq \frac{mn^2 p M^4}{c} 8 \log(2mp/\delta)$$

holds with probability greater than  $1 - \delta$ . The difference between this result and the result of Theorem 1 or its variants such as Lemma 11 is that Lemma 7 guarantees that

every element of the approximation will have small additive error, while Theorem 1 provides a tighter Frobenius norm bound but not elementwise guarantees.

It may seem counterintuitive that by sampling with respect to the optimal probabilities of section 4 the bound of (40) is worse than that of (39) by a factor of  $\sqrt{mp/\beta}$ . (Relatedly, when the nonuniform probabilities of Lemma 7 are used, we have that

$$\|AB - CR\|_F^2 \leq \frac{m^2 n^2 p^2 M^4}{\beta^2 c} 8 \log(2mp/\delta)$$

with probability greater than  $1 - \delta$ .) The reason for this is that the optimal probabilities are optimal with respect to minimizing  $\mathbf{E}[\|AB - CR\|_F^2]$ , in which case elements corresponding to smaller columns and rows contribute relatively little. On the other hand, the two statements of Lemma 7 are required to hold for every  $i$  and  $j$ . Thus (whether or not the uniform probabilities are nearly optimal) because the optimal sampling probabilities bias toward elements corresponding to larger columns and rows an extra factor of  $\sqrt{mp}$  is needed.

### A.3. Analysis of the algorithm for nonnearly optimal probabilities.

Note that the nearly optimal probabilities (7) use information from both matrices  $A$  and  $B$  in a particular form. In some cases, such detailed information about both matrices may not be available. Thus, we present results for the BASICMATRIXMULTIPLICATION algorithm for several other sets of probabilities. See Table 1 in section 6 for a summary of these results.

In the first case, to estimate the product  $AB$  one could use the probabilities (46) which use information from the matrix  $A$  only. In this case  $\|AB - CR\|_F$  can still be shown to be small in expectation, and under an additional assumption the expectation can be removed and the corresponding result can be shown to hold with high probability.

LEMMA 8. *Suppose  $A \in \mathbb{R}^{m \times n}$ ,  $B \in \mathbb{R}^{n \times p}$ ,  $c \in \mathbb{Z}^+$  such that  $1 \leq c \leq n$ , and  $\{p_i\}_{i=1}^n$  are such that  $\sum_{i=1}^n p_i = 1$  and such that*

$$(46) \quad p_k \geq \frac{\beta |A^{(k)}|^2}{\|A\|_F^2}$$

for some positive constant  $\beta \leq 1$ . Construct  $C$  and  $R$  with the BASICMATRIXMULTIPLICATION algorithm, and let  $CR$  be an approximation to  $AB$ . Then

$$(47) \quad \mathbf{E} \left[ \|AB - CR\|_F^2 \right] \leq \frac{1}{\beta c} \|A\|_F^2 \|B\|_F^2.$$

Furthermore, let  $\mathcal{M} = \max_{\alpha} \frac{|B_{(\alpha)}|}{|A_{(\alpha)}|}$ , let  $\delta \in (0, 1)$ , and let  $\eta = 1 + \frac{\|A\|_F}{\|B\|_F} \mathcal{M} \sqrt{(8/\beta) \log(1/\delta)}$ . Then with probability at least  $1 - \delta$ ,

$$(48) \quad \|AB - CR\|_F^2 \leq \frac{\eta^2}{\beta c} \|A\|_F^2 \|B\|_F^2.$$

*Proof.* The proof is similar to that of Theorem 1 except that the indicated probabilities are used.  $\square$

Alternatively, to estimate the product  $AB$  one could use the probabilities (49) which also use information from the matrix  $A$  only, but in a different form than the probabilities (46). In this case, under an additional assumption  $\|AB - CR\|_F$  can still be shown to be small both in expectation and with high probability.

LEMMA 9. Suppose  $A \in \mathbb{R}^{m \times n}$ ,  $B \in \mathbb{R}^{n \times p}$ ,  $c \in \mathbb{Z}^+$  such that  $1 \leq c \leq n$ , and  $\{p_i\}_{i=1}^n$  are such that  $\sum_{i=1}^n p_i = 1$  and such that

$$(49) \quad p_k \geq \frac{\beta |A^{(k)}|}{\sum_{k'=1}^n |A^{(k')}|}$$

for some positive constant  $\beta \leq 1$ . Let  $\mathcal{M} = \max_{\alpha} |B_{(\alpha)}|$ . Construct  $C$  and  $R$  with the BASICMATRIXMULTIPLICATION algorithm, and let  $CR$  be an approximation to  $AB$ . Then

$$(50) \quad \mathbf{E} \left[ \|AB - CR\|_F^2 \right] \leq \frac{1}{\beta c} \|A\|_F^2 n \mathcal{M}^2.$$

Furthermore, let  $\delta \in (0, 1)$  and  $\eta = 1 + \sqrt{(8/\beta) \log(1/\delta)}$ . Then with probability at least  $1 - \delta$ ,

$$(51) \quad \|AB - CR\|_F^2 \leq \frac{\eta^2}{\beta c} \|A\|_F^2 n \mathcal{M}^2.$$

*Proof.* The proof is similar to that of Theorem 1 except that the indicated probabilities are used.  $\square$

The probabilities (46) and (49) depend on only the lengths of the columns of  $A$ . Results similar to those of the previous two lemmas hold if the probabilities depend on the rows of  $B$  rather than the columns of  $A$ ; see Table 1.

Alternatively, to estimate the product of  $AB$  one could use the probabilities (52); interestingly, although the probabilities differ from those of (7) we are able to derive the same bounds as those of Theorem 1 without additional assumptions.

LEMMA 10. Suppose  $A \in \mathbb{R}^{m \times n}$ ,  $B \in \mathbb{R}^{n \times p}$ ,  $c \in \mathbb{Z}^+$  such that  $1 \leq c \leq n$ , and  $\{p_i\}_{i=1}^n$  are such that  $\sum_{i=1}^n p_i = 1$  and such that

$$(52) \quad p_k \geq \frac{\beta |A^{(k)}| |B_{(k)}|}{\|A\|_F \|B\|_F}$$

for some positive constant  $\beta \leq 1$ . Construct  $C$  and  $R$  with the BASICMATRIXMULTIPLICATION algorithm, and let  $CR$  be an approximation to  $AB$ . Then

$$(53) \quad \mathbf{E} \left[ \|AB - CR\|_F^2 \right] \leq \frac{1}{\beta c} \|A\|_F^2 \|B\|_F^2.$$

Furthermore, let  $\delta \in (0, 1)$  and  $\eta = 1 + \sqrt{(8/\beta) \log(1/\delta)}$ . Then with probability at least  $1 - \delta$ ,

$$(54) \quad \|AB - CR\|_F^2 \leq \frac{\eta^2}{\beta c} \|A\|_F^2 \|B\|_F^2.$$

*Proof.* The proof is similar to that of Theorem 1 except that the indicated probabilities are used.  $\square$

Of course one could estimate the product  $AB$  using the uniform probabilities (55). In this case for simplicity we consider bounding  $\|AB - CR\|_F$  directly.

LEMMA 11. Suppose  $A \in \mathbb{R}^{m \times n}$ ,  $B \in \mathbb{R}^{n \times p}$ ,  $c \in \mathbb{Z}^+$  such that  $1 \leq c \leq n$ , and  $\{p_i\}_{i=1}^n$  are such that

$$(55) \quad p_k = \frac{1}{n}.$$

Construct  $C$  and  $R$  with the BASICMATRIXMULTIPLICATION algorithm, and let  $CR$  be an approximation to  $AB$ . Then

$$(56) \quad \mathbf{E} [\|AB - CR\|_F] \leq \sqrt{\frac{n}{c}} \left( \sum_{k=1}^n |A^{(k)}|^2 |B_{(k)}|^2 \right)^{1/2}.$$

Furthermore, let  $\delta \in (0, 1)$  and  $\gamma = \frac{n}{\sqrt{c}} \sqrt{8 \log(1/\delta)} \max_{\alpha} |A^{(\alpha)}| |B_{(\alpha)}|$ . Then with probability at least  $1 - \delta$ ,

$$(57) \quad \|AB - CR\|_F \leq \sqrt{\frac{n}{c}} \left( \sum_{k=1}^n |A^{(k)}|^2 |B_{(k)}|^2 \right)^{1/2} + \gamma.$$

*Proof.* The proof is similar to that of Theorem 1 except that the indicated probabilities are used.  $\square$

**Acknowledgments.** We would like to thank Dimitris Achlioptas for bringing to our attention the results of [21] and the National Science Foundation for partial support of this work. In addition, we would like to thank an anonymous reviewer for providing a careful reading of this paper, for making numerous constructive suggestions, and for bringing [28] to our attention.
