Towards the Realistic, Robust, and Efficient Assessment of Causal Effects with Stochastic Shift Interventions

Considerations for two-phase sampling designs, nonparametric variable importance analysis, and open source software implementations

bit.ly/2018_biostat_quals
- Vaccine efficacy evaluation helps to develop enhanced vaccines better informed by biological properties of the target disease.

- HIV vaccines modulate immune responses as part of the mechanism for lowering HIV risk.

- *Stochastic* interventions provide a flexible framework for considering **realistic** treatment policies.

- Large-scale vaccine trials often use two-phase sampling — need to accommodate such designs.

- We’ve developed robust, open source statistical software for applying stochastic interventions in observational studies.
Motivations and Preliminaries
Motivation: The Burden of HIV-1

- HIV-1 epidemic is in its fourth decade, with 2.5 million new infections occurring annually worldwide.

- Though diminishing, number of newly infected persons outpaces number of patients starting antiretroviral therapy.

- As of 2013, progress is limited: the HIV vaccine efficacy trial with highest impact reported a 31% reduction in infections.

- Careful study led to development of a targeted CD4+ and CD8+ T-cell and antibody boost vaccine, which underwent extensive pre-clinical and early-phase clinical testing.
Motivation: The HVTN 505 Trial

- The HIV Vaccine Trials Network (HVTN) 505 preventive vaccine efficacy trial, detailed in Hammer et al. (2013).

- \( n = 2504 \) participants — all observed cases matched to controls after collection of endpoints of interest.

- Baseline variables (\( W \)): sex, age, BMI, SES, etc.

- Variables of interest (\( A \)): immune response markers (post-vaccination T-cell activity).

- Outcome of interest (\( Y \)): HIV-1 infection status.

- The 505 trial includes both vaccine and placebo arms — we focus on only the vaccine arm (for now).
Interlude: Immune Responses in HVTN 505

- 12-color intracellular cytokine staining (ICS) assay.
- Cryopreserved peripheral blood mononuclear cells were stimulated with synthetic HIV-1 peptide pools.
- Immune responses of interest were
  1. Total magnitude of the CD4\(^+\) T-cell response.
  2. COMPASS Env-specific CD4\(^+\) T-cell polyfunctionality.
  3. Total magnitude of the CD8\(^+\) T-cell response.
  4. COMPASS Env-specific CD8\(^+\) T-cell polyfunctionality.
  5. CD4\(^+\) and CD8\(^+\) T-cell log\(_{10}\)-transformed total magnitude.
- All immune responses are assayed after the endpoints of interest (HIV-1 infection status) are collected.
Motivation: Enhanced Vaccines for HIV-1

- **Question**: How would changes in immune response profile (for a given marker) impact HIV-1 infection?

- Using observational data, thought experiments will allow us to examine scenarios where immune responses were tweaked differently by a given vaccine.

- By isolating potential immune response targets, improved vaccines can be constructed with such targets in mind.

- **Conclusion**: Understanding which immune responses impact vaccine efficacy helps develop more efficacious vaccines.
Consider $X = (W, A, Y) \sim P^X_0 \in \mathcal{M}^X_{NP}$

- $W$ — baseline covariates (e.g., sex, age, etc.),
- $A$ — intervention (e.g., immune response profile post-vaccination),
- $Y$ — outcome of interest (e.g., HIV-1 infection status),
- $P^X_0$ — true (unknown) distribution of the full data $X$,
- $\mathcal{M}^X_{NP}$ — nonparametric statistical model.

Consider observing $X_1, \ldots, X_n$, i.e., $n$ iid copies of $X$.

For now, ignore two-phase sampling design of HVTN 505.
Likelihood Factorization for the Full Data

- Let $q_{0,Y}$ be the conditional density of $Y$ given $(A, W)$ wrt dominating measure $\xi$.

- Let $q_{0,A}$ be the conditional density of $A$ given $W$ wrt dominating measure $\mu$.

- Let $q_{0,W}$ be the density of $W$ wrt dominating measure $\nu$.

- Then, for $p_0^X$, density of $X$ wrt the product measure, density evaluated on a particular observation $x$:

\[
p_0^X(x) = q_{0,Y}^X(y \mid A = a, W = w)q_{0,A}^X(a \mid W = w)q_{0,W}^X(w).
\]
NPSEM for the Full Data

- Use a nonparametric structural equation model (NPSEM) to describe generation of $X$ (Pearl 2009), specifically

\[
W = f_W(U_W) \\
A = f_A(W, U_A) \\
Y = f_Y(A, W, U_Y)
\]

- NPSEM parameterizes $p_X^0$ in terms of the distribution of RVs $(X, U)$ modeled by this system of equations.

- Implies a model for the distribution of counterfactual RVs generated by interventions on the data-generating process.
Our motivations, again: How do changes in a given immune response affect post-vaccination risk of HIV-1 infection?

How does intervening on a given immune response cause changes in HIV-1 risk? How can future vaccines be informed by the lessons we can learn from such thought experiments?

What does it mean to intervene on a continuous-valued quantity? Should one consider setting a specific value deterministically? Perhaps with a dynamic intervention?

Immune responses are surely functions of $W$, and, perhaps, a posited change should depend on $A$ as well.
Science × Software × Statistics
“The origins of the scientific method... amount to insistence on direct evidence. This is reflected in the motto of The Royal Society, founded in 1660: *Nullius in verba*, which roughly means ‘take nobody’s word for it’.” —Philip B. Stark, in *The Practice of Reproducible Research*

- *Show me*, not *trust me* — robust, well documented, rigorously tested software allows others to directly assess our claims.

- The software we distribute allows others to engage with our analysis of the HVTN 505 trial and to apply our method to similar vaccine efficacy trials.

- We will be making *causal* claims about vaccine efficacy. Our results could be medically impactful, so reproducibility is vital.
What’s wrong with that code I wrote that one time?

“An article...in a scientific publication is not the scholarship itself, it is merely advertising of the scholarship. The actual scholarship is the complete software development environment and the complete set of instructions which generated the figures.” —David Donoho, on *WaveLab*

- Reproducible applied statistics *requires robust software*:
  - Clear, easily accessible documentation, including examples.
  - Unit testing to rigorously assess functions, classes, etc.
  - Continuous integration, ensuring accessibility across systems and constant monitoring of software quality.
  - Open source development, embodying an ongoing, continuous, public peer review of the software product.
A new software environment and framework for Targeted Learning, with a focus on extensibility.

**Goal:** expose a set of design principles off of which all future Targeted Learning software will be built.

**How?** A core framework, plus minimal extensions ("connector packages"), each implementing a few estimators.
Towards Stochastic Interventions
A static intervention replaces $f_A$ with a specific value $a$ in the support of $q_{0,A}(\cdot \mid W)$ a.e. $q_{0,W}$.

This requires specifying a particular value of the intervention (i.e., $A = a$) under which to evaluate the outcome.

Is it really sensible to set the value of an immune response to a particular value? (Even as a function of $W$.)

This is statistically accessible but scientifically uninteresting (perhaps dishonest, even) — one would have to test many different values $a$, with only intuition as a guide.
Interlude: A Linear Modeling Perspective

- Briefly consider a simple data structure: $X = (Y, A)$; we seek to model the outcome $Y$ as a function of $A$.

- To posit a linear model, consider $Y_i = \beta_0 + \beta_1 A_i + \epsilon_i$, with error $\epsilon_i \sim N(0, 1)$.

- Letting $\delta$ be a change in $A$, $Y_{A+\delta} - Y_A$ may be expressed

$$
EY_{A+\delta} - EY_A = [\beta_0 + \beta_1(EA + \delta)] - [\beta_0 + \beta_1(EA)]
= \beta_0 - \beta_0 + \beta_1 EA - \beta_1 EA + \beta_1 \delta
= \beta_1 \delta
$$

- Thus, a *unit shift* in $A$ (i.e., $\delta = 1$) may be seen as inducing a change in the difference in outcomes of magnitude $\beta_1$. 
Interlude: A Causal Inference Perspective

- Consider a data structure: \((Y_a, a \in A)\).

- To posit a linear model, let \(Y_a = \beta_0 + \beta_1 a + \epsilon_a\) for \(a \in A\), with error \(\epsilon_a \sim N(0, \sigma_a^2) \forall a \in A\).

- For the counterfactual outcomes \((Y_a', Y_{a'})\), their difference, \(Y_{a'+\delta} - Y_{a'}\), for some \(a' \in A\), may be expressed

\[
E(Y_{a'+\delta}) - E(Y_{a'}) = [(\beta_0 + \beta_1 (a' + \delta) + E\epsilon_{a'+\delta})] - [\beta_0 + \beta_1 a' + E\epsilon_{a'}] = \beta_1 \delta
\]

- Thus, a unit shift for \(a' \in A\) (i.e., \(\delta = 1\)) may be seen as inducing a change in the difference in the counterfactual outcomes of magnitude \(\beta_1\).
Stochastic Interventions in our NPSEM

- *Stochastic interventions* modify the value \( A \) would naturally assume, \( f_A(W, U_A) \), by drawing from a modified intervention distribution \( G^*(\cdot | W) \) so that the new value \( A^* \sim G^*(\cdot | W) \).

- This generates a counterfactual RV, with distribution \( P^d_0 \),
  \[
  Y_{d(A,W)} := f_Y(d(A, W), W, U_Y) \equiv Y_{G^*} := f_Y(A^*, W, U_Y).
  \]

- We estimate \( \psi_{0,d} := \mathbb{E}_{P^d_0}\{Y_{d(A,W)}\} \), mean of \( Y_{d(A,W)} \).

- For HVTN 505, \( \psi_{0,d} \) is the counterfactual risk of HIV-1 infection, had the observed value of the immune response been altered under the rule \( d(A, W) \) defining \( G^*(\cdot | W) \).

- Helps isolate immune responses that causally inhibit HIV-1; future vaccines may be designed to target these markers.
Proposal: Evaluate outcome under an altered intervention distribution — e.g., \( P_\delta(g_0)(A = a \mid W) = g_0(a - \delta(W) \mid W) \).

Identification conditions for a statistical parameter of the counterfactual outcome \( \psi_{0,d} \) under such an intervention.

Show that the causal quantity of interest \( \mathbb{E}_0\{ Y_{d(A,W)} \} \) is identified by a functional of the distribution of \( X \):

\[
\psi_{0,d} = \int \int \mathbb{E}_{P_0^X}\{ Y \mid A = d(a, w), W = w \} \cdot q_{0,A}^X(a \mid W = w) \cdot q_{0,W}(w)d\mu(a)d\nu(w)
\]

Provides a derivation based on the efficient influence function (EIF) with respect to the nonparametric model \( \mathcal{M} \).
Proposal: Characterization of stochastic interventions as modified treatment policies (MTPs).

Assumption of piecewise smooth invertibility allows for the intervention distribution of any MTP to be recovered:

\[ g_{0,\delta}(a \mid w) = \sum_{j=1}^{J(w)} I_{\delta,j}\{h_j(a, w), w\} g_{0,\delta}\{h_j(a, w) \mid w\} h_j'(a, w) \]

Such intervention policies account for the natural value of the intervention A directly yet are interpretable as the imposition of an altered intervention mechanism.

Identification conditions for assessing the parameter of interest under such interventions appear technically complex (at first).
• Builds on the original proposal, accommodating MTP-type shifts \( d(A, W) \) proposed after their earlier work.

• To protect against positivity violations, considers a specific shifting mechanism:

\[
d(a, w) = \begin{cases} 
  a + \delta, & a + \delta < u(w) \\
  a, & \text{otherwise}
\end{cases}
\]

• Proposes an improved “1-TMLE” algorithm, with a single auxiliary covariate for constructing the TML estimator.

• Our (first) contribution: implementation of this algorithm.
Assumption 1: *Consistency*

\[ Y_i^{d(a_i,w_i)} = Y_i \text{ in the event } A_i = d(a_i, w_i), \text{ for } i = 1, \ldots, n \]

Assumption 2: *SUTVA*

\[ Y_i^{d(a_i,w_i)} \text{ does not depend on } d(a_j, w_j) \text{ for } i = 1, \ldots, n \text{ and } j \neq i, \text{ or lack of interference} \ (\text{Rubin 1978; 1980}) \]

Assumption 3: *Strong ignorability*

\[ A_i \perp Y_i^{d(a_i,w_i)} | W_i, \text{ for } i = 1, \ldots, n \]
Assumption 4: *Positivity (or overlap)*

\[ a_i \in \mathcal{A} \implies d(a_i, w_i) \in \mathcal{A} \text{ for all } w \in \mathcal{W}, \text{ where } \mathcal{A} \text{ denotes the support of } \mathcal{A} \text{ conditional on } W = w_i \text{ for all } i = 1, \ldots, n \]

- This positivity assumption is not quite the same as that required for categorical interventions.
- In particular, we do not require that the intervention density place mass across all strata defined by \( \mathcal{W} \).
- Rather, we merely require the post-intervention quantity be seen in the observed data for given \( a_i \in \mathcal{A} \) and \( w_i \in \mathcal{W} \).
Now we have the statistical functional (target parameter):

$$\Psi(P_0^X) = \mathbb{E}_{P_0^X} \overline{Q}(d(A, W), W),$$

allowing estimation of causal parameter $$\psi_{0,d} = \mathbb{E} Y_{d(A, W)}$$.

We now seek to efficiently estimate this target parameter in the nonparametric model $$\mathcal{M}$$.

We implement a targeted minimum loss-based estimator of this statistical target parameter.
Interlude: Slope in a Semiparametric Model

- Consider the stochastic intervention \( g^*(\cdot \mid W) \):
  \[
  \mathbb{E} Y_{g^*} = \int_\mathcal{W} \int_a \mathbb{E}(Y \mid A = a, W) g(a - \delta \mid W) \cdot da \cdot dP_0(W) = \int_\mathcal{W} \int_z \mathbb{E}(Y \mid A = z + \delta, W) g(z \mid W) \cdot dz \cdot dP_0(W),
  \]
  defining the change of variable \( z = a - \delta \).

- For a semiparametric model, \( \mathbb{E}(Y \mid A = z, W) = \beta z + \theta(W) \):
  \[
  \mathbb{E} Y_{g^*} - \mathbb{E} Y = \int_\mathcal{W} \int_z \left[ \mathbb{E}(Y \mid A = z + \delta, W) - \mathbb{E}(Y \mid A = z, W) \right] g(z \mid W) \cdot dz \cdot dP_0(W)
  = [\beta(z + \delta) + \theta(W)] - [\beta z + \theta(W)]
  = \beta \delta
  \]
Targeted Minimum Loss-Based Estimation

- A TMLE is an algorithm for updating initial estimators so as to satisfy an arbitrary set of estimating equations.
- Semiparametric-efficient estimation thru solving efficient influence function estimating equation wrt the model $M$.
- Statistical target parameter: $\Psi(P_0^X) = \mathbb{E}_{P_0^X} \overline{Q}(d(A,W), W)$
- For which the efficient influence function (EIF) is
  \[ D(P_0^X)(x) = H(a, w)(y - \overline{Q}(a, w)) + \overline{Q}(d(a, w), w) - \Psi(P_0^X) \]
- The auxiliary covariate $H(a, w)$ may be expressed
  \[ H(a, w) = \mathbb{I}(a + \delta < u(w)) \frac{g_0(a - \delta \mid w)}{g_0(a \mid w)} + \mathbb{I}(a + \delta \geq u(w)) \]
Key Properties of TML Estimators

- **Asymptotic linearity:**

\[
\psi(P^*_n) - \psi(P^X_0) = \frac{1}{n} \sum_{i=1}^{n} D(P^X_0)(X_i) + o_P\left(\frac{1}{\sqrt{n}}\right)
\]

- **Gaussian limiting distribution:**

\[
\sqrt{n}(\psi(P^*_n) - \psi(P^X_0)) \rightarrow N(0, \text{Var}(D(P^X_0)(X)))
\]

- **Statistical inference:**

Wald-type CI: \(\psi(P^*_n) \pm z_\alpha \cdot \frac{\sigma_n}{\sqrt{n}}\),

where \(\sigma^2_n\) is computed directly via \(\sigma^2_n = \frac{1}{n} \sum_{i=1}^{n} D^2(\cdot)(X_i)\).
Algorithm for TML Estimation

1. Construct initial estimators $g_n$ of $g_0(A, W)$ and $Q_n$ of $Q_0(A, W)$, perhaps using data-adaptive regression techniques.

2. For each observation $i$, compute an estimate $H_n(a_i, w_i)$ of the auxiliary covariate $H(a_i, w_i)$.

3. Estimate the parameter $\epsilon$ in the logistic regression model

   \[
   \logit \overline{Q}_{\epsilon,n}(a, w) = \logit \overline{Q}_n(a, w) + \epsilon H_n(a, w),
   \]

   or an alternative regression model incorporating weights.

4. Compute TML estimator $\Psi_n$ of the target parameter, defining update $\overline{Q}^*_n$ of the initial estimate $\overline{Q}_{n,\epsilon_n}$:

   \[
   \Psi_n = \Psi(P^*_n) = \frac{1}{n} \sum_{i=1}^{n} \overline{Q}^*_n(d(A_i, W_i), W_i).
   \]
Software package: R/s13

Simulation Study: TML Estimation

- For a single observational unit \( X = (W, A, Y) \), data are simulated using the following set of structural equations:
  
  \[
  W \sim \text{Bern}(p = 0.5) \\
  A \sim \mathcal{N}(\mu = \gamma \cdot W, \sigma^2 = 1) \\
  Y = A + W + \epsilon,
  \]

- Let \( \gamma = 2 \) be a multiplier of the effect of the baseline covariate \( W \) on the natural value of the treatment \( A \), and white noise \( \epsilon \sim \mathcal{N}(0, 1) \).

- We consider the case of observing a data structure composed of \( n \) replicates of \( X \), i.e., \( X_1, \ldots, X_n \).

- Letting \( \delta = 0.5 \), we construct a TML estimate of the counterfactual mean outcome \( \psi_{0,d} \).

Software package: R/tmle3shift

Figure 3: https://github.com/tlverse/tmle3shift

- Tools for assessing the effects of stochastic interventions.
- Supports interventions that enforce positivity constraints.
- First of many “connector” R packages that extend the tlverse ecosystem.
Two-Phase Sampling Designs
In the 505 HIV-1 trial, all infected individuals are matched to controls after endpoints are collected.

We need to extend our full data structure \( X = (W, A, Y) \) to accommodate such a sampling procedure.

Consider the observed data structure \( O = (W, \Delta, \Delta A, Y) \), a masked version of the full data structure.

Let \( \Delta = f(Y, W) \) be binary s.t. \( \Delta \in \{0, 1\} \), where \( \Delta = 1 \) corresponds to being selected into the second-stage sample.

Let \( \pi_0(Y, W) = \mathbb{P}(\Delta = 1 \mid Y, W) \), and let \( \pi_n(Y, W) \) be an estimator of \( \pi_0(Y, W) \).
• Rose and van der Laan (2011) introduce the IPCW-TMLE, to be used when observed data is subject to two-phase sampling.

• Their proposal constructs estimators for an observed data structure of the form $O = (V, \Delta, \Delta X)$.

• In our use-case, the sampling node $V = \{Y, W\}$, and thus we have our proposed data structure $O = (W, \Delta, \Delta A, Y)$.

• Initial proposal: correct for two-phase sampling by using an IPC-weighted loss function:

$$\mathcal{L}(P_0^X)(O) = \frac{\Delta}{\pi_n(Y, W)} \mathcal{L}^F(P_0^X)(X)$$
When the sampling mechanism is not known by design, it is best to employ a nonparametric estimator of $\pi_0(Y, W)$.

When $\pi_0(Y, W)$ is estimated nonparametrically, the IPCW augmentation must be applied to the EIF:

$$D(P_0^X)(o) = \frac{\Delta}{\pi_0(y, w)} D^F(P_0^X)(x)$$

$$- \left(1 - \frac{\Delta}{\pi_0(y, w)}\right) \mathbb{E}(D^F(P_0^X)(x) \mid \Delta = 1, Y = y, W = w),$$

expressed in terms of the full data EIF $D^F(P_0^X)(x)$. 
The IPC-augmented EIF points out two distinct terms:

\[
\frac{\Delta}{\pi_0(y,w)} D^F(P_0^X)(x)
\]

The IPC-weighted EIF of the full data structure \(X\), relative to the nonparametric model \(M\); and, 

\[
\left(1 - \frac{\Delta}{\pi_0(y,w)}\right) \mathbb{E}(D^F(P_0^X)(x) \mid \Delta = 1, Y = y, W = w)
\]

The expectation of the full data EIF \(D^F(P_0^X)(x)\), taken only over units selected by the sampling mechanism (i.e., \(\Delta = 1\)).
Emergent Property: Multiple Robustness

- We now have a semiparametric-efficient and robust procedure for assessing the effect of the intervention $d(a, w) = a + \delta$.

- Due to the construction of the IPCW-TMLE, the resultant estimator is robust and efficient under two-phase sampling.

- Uniquely, a multiple robustness property emerges — through combinations of $(g, Q)$ and $(\pi(Y, W), \mathbb{E}(D^F(P_0^X)(x) \mid Y, W))$.

- This allows us to assess how posited shifts in the assayed immune responses would have affected HIV-1 infection risk.
For a single observational unit $O = (W, \Delta, \Delta A, Y)$, data are simulated using the following set of structural equations:

\[
\begin{align*}
W_1 & \sim N(\mu = 3, \sigma^2 = 1) \\
W_2 & \sim Bern(p = 0.6) \\
W_3 & \sim Bern(p = 0.3) \\
A & \sim N(\mu = 2 \cdot (W_2 + W_3), \sigma^2 = 1) \\
Y & = Bern \left( p = \frac{1 + \tanh \left( \frac{W_1 + W_2 + W_3 - A}{3} \right)}{2} \right) \\
\Delta & = Bern \left( p = \frac{1 + \tanh \left( \frac{W_1 + W_2 + W_3 - Y}{3} \right)}{2} \right)
\end{align*}
\]
Simulation Study: IPC-Weighted TML Estimation

- We consider the case of observing a data structure composed of \( n \) replicates of \( O \), i.e., \( O_1, \ldots, O_n \).

- Letting \( \delta = 0.5 \), we construct an IPCW-TML estimate of the counterfactual mean outcome \( \psi_{0,d} \) for \( P_{X}^{X} \), the data generating distribution of the full data \( X \) from which \( O \) is derived.

- **Goal:** Assess extent to which fitting sampling mechanism with a nonparametric regression affects the resultant estimator.
  1. Fit \( \pi_0(Y, W) \) with a GLM or the Highly Adaptive Lasso (HAL), building loss-augmented and EIF-augmented TMLEs.
  2. Compare bias, variance, and relative efficiency of the resultant TML estimators.

Software package: R/txshift

**Figure 4:** https://github.com/nhejazi/txshift

- Supports estimation of the effects of simple (additive) stochastic interventions.
- Implements both types of IPCW-TML estimator, allowing for two-phase sampling to be appropriately handled when $\pi_0(V)$ is known by design or unknown.
Extensions and Future Directions
Ongoing Efforts

- Extensions of stochastic interventions to causal mediation analysis — new theory provides estimators of the *natural direct effect* and the *natural indirect effect*.
  - Collaboration with Iván Díaz (Cornell) in progress.

- Further refinement of the *tlverse* software ecosystem, including new “connector” R packages.

- Data analysis of the HVTN 505 HIV-1 vaccine trial, and discussion of the scientific findings with scientist collaborators.
Future Directions

- Exploration of different forms of stochastic interventions — Kennedy (2018) proposes a shift in propensity scores for binary (or categorical) interventions.
  - Implementation in the tlverse ecosystem.

- Refinements of statistical theory so as to better work with quantities common in survival analysis: hazards? survival?

- Assessment of newly concluded and ongoing efficacy trials through work with ongoing collaborators at Fred Hutch.
### Software and Statistics Revisited

- **Software is not** an ancillary activity: How can a theorem or result impact science if no one can apply it?
- **Writing software is important for learning statistics:**
  - How do people plan to use the software?
  - What is the problem that the software solves?
  - What’s the “best” way to estimate the quantity of interest?
- **Writing software impacts** statistics — minor tweaks to implemented estimators help us discover new ideas.
Review: Summary

- Vaccine efficacy evaluation helps to develop enhanced vaccines better informed by biological properties of the target disease.
- HIV vaccines modulate immune responses as part of the mechanism for lowering HIV risk.
- *Stochastic* interventions provide a flexible framework for considering **realistic** treatment policies.
- Large-scale vaccine trials often use two-phase sampling — need to accommodate such designs.
- We’ve developed robust, open source statistical software for applying stochastic interventions in observational studies.

Appendix
Literature: Young et al. (2014)

- Establishes equivalence between g-formula when proposed intervention depends on natural value and when it does not.
- This equivalence leads to a sufficient positivity condition for estimating the counterfactual mean under MTPs via the same statistical functional studied in Díaz and van der Laan (2012).
- Extends earlier identification results, providing a way to use the same statistical functional to assess $\mathbb{E} Y_{d(A, W)}$ or $\mathbb{E} Y_{d(W)}$.
- The authors also consider limits on implementing shifts $d(A, W)$, and address working in a longitudinal setting.
To compute the auxiliary covariate $H(a, w)$, we need to estimate conditional densities $g(A \mid W)$ and $g(A - \delta \mid W)$.

There is a rich literature on density estimation, we follow the approach proposed in Díaz and van der Laan (2011).

To build a conditional density estimator, consider

$$g_{n, \alpha}(a \mid W) = \frac{P(A \in [\alpha_{t-1}, \alpha_t] \mid W)}{\alpha_t - \alpha_{t-1}},$$

for $\alpha_{t-1} \leq a < \alpha_t$.

This is a classification problem, where we estimate the probability that a value of $A$ falls in a bin $[\alpha_{t-1}, \alpha_t]$.

The choice of the tuning parameter $t$ corresponds roughly to the choice of bandwidth in classical kernel density estimation.
Díaz and van der Laan (2011) propose a re-formulation of this classification approach as a set of hazard regressions.

To effectively employ this proposed re-formulation, consider

\[
P(A \in [\alpha_{t-1}, \alpha_t] \mid W) = P(A \in [\alpha_{t-1}, \alpha_t] \mid A \geq \alpha_{t-1}, W) \times \\
\prod_{j=1}^{t-1} \{1 - P(A \in [\alpha_{j-1}, \alpha_j] \mid A \geq \alpha_{j-1}, W)\}
\]

The likelihood of this model may be expressed to correspond to the likelihood of a binary variable in a data set expressed via a long-form repeated measures structure.

Specifically, the observation of \( X_i \) is repeated as many times as intervals \([\alpha_{t-1}, \alpha_t]\) are before the interval to which \( A_i \) belongs, and the binary variables indicating \( A_i \in [\alpha_{t-1}, \alpha_t] \) are recorded.
To estimate $g(A \mid W)$ and $g(A - \delta \mid W)$, use a pooled hazard regression, spanning the support of $A$.

We rely on the Super Learner algorithm of van der Laan et al. (2007) to build an ensemble learner that optimally weights each of the proposed regressions, using cross-validation (CV).

The Super Learner algorithm uses $V$-fold CV to train each proposed regression model, weighting each by the inverse of its average risk across all $V$ holdout sets.

By using a library of regression estimators, we invoke the result of van der Laan et al. (2004), who prove this likelihood-based cross-validated estimator to be asymptotically optimal.
Algorithm for IPCW-TML Estimation

1. Using all observed units \((X)\), estimate sampling mechanism \(\pi(Y, W)\), perhaps using data-adaptive regression methods.

2. Using only observed units in the second-stage sample \(\Delta = 1\), construct initial estimators \(g_n(A, W)\) and \(Q_n(A, W)\), weighting by the sampling mechanism estimate \(\pi_n(Y, W)\).

3. With the approach described for the full data case, compute \(H_n(a_i, w_i)\), and fluctuate submodel via logistic regression.

4. Compute IPCW-TML estimator \(\Psi_n\) of the target parameter, by solving the IPCW-augmented EIF estimating equation.

5. Iteratively update estimated sampling weights \(\pi_n(Y, W)\) and IPCW-augmented EIF, updating TML estimate in each iteration, until \(\frac{1}{n} \sum_{i=1}^{n} EIF_i < \frac{1}{n}\).
Consider a more sophisticated shift function:

\[
\delta(a, w) = \begin{cases} 
\delta, & \delta_{\min}(a, w) \leq \delta \leq \delta_{\max}(a, w) \\
\delta_{\max}(a, w), & \delta \geq \delta_{\max}(a, w) \\
\delta_{\min}(a, w), & \delta \leq \delta_{\min}(a, w)
\end{cases}
\]

where we define maximal and minimal possible shifts:

\[
\delta_{\max}(a, w) = \arg\max \left\{ \delta \geq 0, \frac{g(a-\delta|w)}{g(a|w)} \leq M \right\} \frac{g(a-\delta|w)}{g(a|w)}
\]

and

\[
\delta_{\min}(a, w) = \arg\min \left\{ \delta \leq 0, \frac{g(a-\delta|w)}{g(a|w)} \leq M \right\} \frac{g(a-\delta|w)}{g(a|w)}.
\]
Consider now a grid of $j$ possible shift values $\delta$, where we seek to estimate the counterfactual mean under each value of $\delta$.

With this approach, we construct $j$ estimates $\psi_{n,j}$ of the counterfactual mean, each under a different proposed value of the shift $\delta_j$.

We may summarize $\psi_{n,j}$ through a working marginal structural model (MSM), constructing inference through a hypothesis test of the a parameter of the MSM.

Formally, let $\vec{\psi}_\delta = (\psi_\delta : \delta)$ with corresponding estimators $\vec{\psi}_{n,\delta} = (\psi_{n,\delta} : \delta)$. Further, let $\beta(\vec{\psi}_\delta) = \phi((\psi_\delta : \delta))$.
Variable Importance Analysis with MSMs

- For a given MSM $m_\beta(\delta)$, we have that

$$\beta_0 = \arg\min_\beta \sum_\delta (\psi_\delta(P_0) - m_\beta(\delta))^2 h(\delta),$$

- This then leads to the following expansion

$$\beta(\vec{\psi}_n) - \beta(\vec{\psi}_0) \approx -\frac{d}{d\beta} u(\beta_0, \vec{\psi}_0)^{-1} \frac{d}{d\psi} u(\beta_0, \psi_0)(\vec{\psi}_n - \vec{\psi}_0),$$

- In terms of the efficient influence function (EIF) of $\psi$ by using the first order approximation

$$(\psi_n - \psi_0)(\delta) = \frac{1}{n} \sum_{i=1}^n EIF_{\psi_\delta}(O_i),$$

where $EIF_{\psi_\delta}$ is the efficient influence function (EIF) of $\vec{\psi}$
Now, say, $\tilde{\psi} = (\psi(\delta) : \delta)$ is d-dimensional, then we may write the efficient influence function of the MSM parameter $\beta$ (assuming a linear MSM) as follows

$$\text{EIF}_{\beta}(O) = \left( \sum_{\delta} h(\delta) \frac{d}{d\beta} m_{\beta}(\delta) \frac{d}{d\beta} m_{\beta}(\delta)^t \right)^{-1} \cdot \sum_{\delta} h(\delta) \frac{d}{d\beta} m_{\beta}(\delta) \text{EIF}_{\psi_\delta}(O),$$

where the first term is of dimension $d \times d$ and the second term is of dimension $d \times 1$.
